crust. The American geologist Harry Hess provided decisive input in the understanding of plate tectonics in the beginning of 1950 when he used a magnetometer to record magnetic variations across the ocean floor. These magnetic variations are associated with the magnetite contained in oceanic basalts, which records the orientation and intensity of the Earth's magnetic field at the time of basalt extrusion. Most importantly, magnetic studies revealed the existence of alternating stripes of normal and reverse polarity which are symmetrically distributed on either side of the mid-ocean ridge (Vine and Matthews 1963). The alternation of normally and reversely polarized bands, called magnetic striping, led to the theory of sea-floor spreading. In the 1960s, it was suggested that the mid-ocean ridges mark structurally weak zones where the ocean floor was split in two along the ridge crest. It was suggested that pulses of magma rise along the ridge and create new oceanic crust which then migrate laterally away from the ridge – the process called sea-floor spreading. The alternation of direct and inverse magnetic polarity is related to periodical changes in the polarity of the Earth's magnetic field, which is recorded in the basaltic rocks. The explanation of the magnetic striping led to the rapid acceptance of sea-floor spreading as a key element of plate tectonics theory.

A consequence of sea-floor spreading is that new crust is continuously formed. Carey (1958) used this concept to propose a model of Earth expansion, then Hess (1962) suggested that if the ocean floor is expanding along ridges, it must be removed at oceanic trenches, the deep valleys rimming the Pacific Ocean. In other words, as new crust forms at oceanic ridges by magma accretion, old crust is destroyed along trenches – in oceanic subduction zones. The modern theory of plate tectonics proposes that the continents are not moving through oceanic crust (as in the continental drift concept of Wegener) but that oceanic crust and in some cases attached continents move together on the same crustal unit called a “plate.” Soon after, plate tectonics evolved significantly with the recognition of transform faults by the Canadian geologist Tuzo Wilson (1965). In his model, the oceans are created, grow, and

disappear; and the continents are fragmented, separated, and reassembled in what are now called “Wilson cycles.”

Further understanding of plate kinematics came from the work of the American geophysicist William Jason Morgan (1968), who explained relative displacements of two adjacent plates. He showed that the movements are parallel to transform faults and centered on a pole of rotation (the Euler pole), and that variations of sea-floor expansion are a function of the distance from the pole of rotation. Xavier Le Pichon (1968) built on Morgan's concept and proposed a kinematic reconstruction of the formation of the Atlantic and Indian oceans within the frame of six rigid plates including continental masses. Geological aspects of the theory of plate tectonics were developed by Dewey and Bird (1970), who showed that the structure of active continental margins is dependent on the geometry and kinematics of subduction zones. This seminal paper showed geologists how the orogenic belts are linked to movements of the oceanic lithosphere, and explained the relationship between plate tectonics and both the complex three-dimensional movements at continental margins and the magmatic and metamorphic processes of mountain building.

Basic Methodology

Three methods had a decisive impact on the development and further understanding of plate boundaries: seismology, ► [paleomagnetism](#), and modern paleoclimatic and paleobiogeographic studies.

Seismology

Seismology developed rapidly in the twentieth century with the construction of seismographs that enabled geophysicists to understand the Earth's internal structure, the composition of continental and oceanic crust, and the boundary between the crust and mantle – the so-called Mohorovičić discontinuity or ► [“Moho”](#), named after its discoverer, the Croatian seismologist Andrija Mohorovičić. The second major discovery was that earthquakes tend to be located along

plate boundaries, from the oceanic trenches downwards, as well as along the spreading ridges and transform faults. The seismologists Hugo Benioff of the California Institute of Technology and Kiyoo Wadati of the Japan Meteorological Agency independently identified earthquake zones that were several hundred kilometers long, oriented parallel to the trenches, and dipping at 40° – 60° – the so-called Wadati-Benioff or subduction zones.

Paleomagnetism

Paleomagnetism is the study of the record of the Earth's past magnetic field as preserved in magnetic minerals in rocks. The principle is based on the fossilization of the magnetic field direction at the time of cooling of lavas or deposition of sediments. It is possible to measure the orientation, the polarity, and sometimes even the intensity of the magnetic field. Knowing the magnetic field at the given time allows us to reconstruct the apparent position of the pole and consequently the latitude and orientation of the studied region at a given time. This method has played a decisive role in obtaining a better understanding of the movement and rotation of plates, and the migration of continents over long periods of time. Further, the discovery of magnetic stripes on the ocean floor was decisive for understanding the opening of the oceans and helpful for formulating the new theory of plate tectonics.

Tectonic and Paleobiogeographic Reconstructions

Paleomagnetic studies are intimately connected with tectonic, paleobiogeographic, and paleoclimatological syntheses. It was shown that the drift of continents across paleo-latitudes was responsible for deposition of climatically sensitive sediments such as evaporites or tillites. In addition, continental drift played a decisive role in the distribution, diversity, and extinction of past life. Continents may break up, separate, and subsequently collide, thereby changing the disposition of faunal provinces and barriers to faunal migration. Paleobiogeographic studies bring key information about the isolation or connection of continents, the position of suture zones and

ancient oceans, and the paleogeographic position of lithospheric plates.

Structure of Lithospheric Plates

The outer layers of the Earth are divided into the ► **lithosphere** and ► **asthenosphere**. The distinction is based on differences in mechanical properties and in the process of heat transfer. The concept of lithosphere was introduced by Barell (1914) on the basis of geological and physical evidence suggesting the existence of a strong superficial layer (the lithosphere) floating above a weak zone (the asthenosphere). The lithosphere is defined as a mobile, near-surface, strong layer with a viscosity of about $10^{24} \text{ Pa s}^{-1}$ (Isacks et al. 1968) that supports high differential stress. The asthenosphere, in contrast, already flows under low stresses and has a disproportionally lower viscosity of 10^{20} – $10^{21} \text{ Pa s}^{-1}$. Consequently, earthquakes occur within the lithosphere but not in the asthenosphere, except where lithospheric slabs sink into the asthenosphere in subduction or collisional zones. As a first approximation, the lithospheric plate can be considered to be an elastic or viscoelastic sheet. The thickness of a plate is also the thickness of the lithosphere, which, at any location, is composed of continental (granitic to granodioritic) or oceanic (basaltic) crust and the subcrustal (peridotitic) mantle. The lithosphere loses heat by conduction, whereas the asthenosphere transfers heat mainly by convection and has a nearly adiabatic temperature gradient. Therefore, the contact between the lithosphere and the asthenosphere is not to a chemical or mineralogical boundary but a strong contrast of rheological behavior dependent on temperature. Two isotherms define this contact. The first, at 1,270–1,340 °C, corresponds to the temperature of the beginning of partial melting of the mantle peridotite as a function of lithostatic pressure. Partial melting of peridotite has been invoked to explain a layer with reduced seismic velocities – the low-velocity zone or LVZ – at the base of the lithosphere. The second isotherm, at 1,100–1,200 °C, corresponds to the temperature at which the deformation mechanism of mantle olivine changes from dislocation creep to diffusional creep.

In the oceans, the lithosphere thickens from the mid-ocean ridge (<20 km) to up to 100 km beneath older oceanic basins. It is even thicker beneath the continents, ranging from 120 to 250 km underneath old, cold, rigid Archean cratonic crust. The lithosphere under continents is thinner in tectonic regions such as active margins and intracontinental rifts where hot material may exist at shallow depth, and is thicker underneath orogenic belts where the lithosphere-asthenosphere boundary is depressed by thickening of the crust and mantle lithosphere.

Plate Boundaries and Hot Spots

Three main types of plate boundaries exist, each characterized by different relative motions of adjacent plates. Plate boundaries are marked by different tectonic processes and are associated with seismic and magmatic activities. The sites of localized mantle melting, called hot spots, are marked by chains of volcanoes aligned within plates in a direction parallel to plate movement.

Divergent Boundaries

Divergent boundaries occur where two plates move apart from one another. These boundaries, called mid-ocean ridges, are marked by bathymetric highs over the 4,000 m isobath within all the oceans. Here, new oceanic crust is formed by the eruption and crystallization of tholeiitic magmas (MORB, Mid Ocean Ridge Basalt), issued from 10% to 20% partial melting of mantle peridotite.

The thickness of the oceanic crust, as determined by seismic experiments (away from the fracture zones and from hot spot influence), varies between 2 and 8 km. With the exception of ultraslow-spreading ridges, the mean thickness of the oceanic crust is 6 km (White et al. 2001). Seismic activity on the ridges is superficial (the depth of earthquake hypocenters is 9 km, close to the brittle-ductile transition), with low magnitude (<6 M) and characterized by extensional focal mechanism. The ridge segments are truncated by transform faults that may reach tens to hundreds of kilometers long (see below). The larger transform faults exhibit high relief and intense seismic activity, with mainly strike-slip focal mechanisms between the ridge segments.

The spreading rate is calculated using magnetic anomalies. These originate from thermo-remnant magnetization of the basaltic crust, registered by Fe-oxides. Magnetic anomalies produce a striped pattern in the oceanic crust that results from changes from normal (in the same direction as the present magnetic field) to inverse (in the opposite direction compared to the present) polarity of the Earth's field at the time of crystallization. The ages of these anomalies have been established by dating of sediments deposited on magnetized blocks and collected during ocean drilling programs (DSDP, ODP, and IODP) or by dating of the volcanic rocks themselves. The anomalies are numbered from 1 to 34, corresponding to the period from the present to the Cretaceous normal quiet period from 84 to 118 Ma. For the older periods, the anomalies have been denoted M0 (118 Ma) to M41 (166 Ma). The anomalies are identified and modeled by measuring the direction of the regional magnetic field, its depth, and the thickness and direction of magnetization of the magnetic layer. Anomalies are present on both sides of the spreading zone but are not always symmetrical. The full spreading rate is calculated using the distance between isochrons of the same age on opposing sides of the ridge and the half spreading rate is defined using the isochrons on only one side (Hellinger 1981).

The spreading rate is variable from one ridge to another. Mid-ocean ridges are classified as ultraslow (0.8–1.5 cm year⁻¹), slow (1.5–5 cm year⁻¹), intermediate (5–9 cm year⁻¹), and fast (9–20 cm year⁻¹) (Fig. 1; plate velocities, from Westphal et al. 2002). Spreading rates increase along the ridge away from the position of the Euler pole to the equator. Spreading rates vary through time due to changes in plate motions (e.g., at 17–12 cm year⁻¹ during the period 70–45 Ma, to 4 cm year⁻¹ during the period 45 Ma to Recent on the SE Indian ridge as a result of the India-Eurasia collision).

Away from the influence of hot spots, the physical parameters of ridges depend on the spreading rate (MacDonald 1982). Slow-spreading ridges exhibit a narrow axial relief (below the 3,000 m isobath) with a pronounced axial valley and rugged transverse and along-axis

Plate Tectonics, Fig. 1 Directions and full spreading rates (cm year^{-1}) for ridges and direction and shortening rates for subduction zones (Westphal et al. 2002)

segmented morphologies with large variations in height (Fig. 2a; slow-spreading ridge from Pomerol et al. 2005). Their magma budget is low and mantle peridotite is frequently exposed at the surface. Axial magma chambers have not been detected. Large amplitude mantle gravity anomalies beneath slow-spreading ridges are of “bull eyes” shape. In contrast, fast-spreading ridges exhibit a large axial relief with an axial dome and smoother transverse and along-axis morphologies (Fig. 2b; fast-spreading ridges from Pomerol et al. 2005). Their magma flux is high and an axial magma chamber may be seismically detected. The lithosphere remains thin beneath the flanks of the ridge up to a distance corresponding to 40 Ma. Low-amplitude mantle gravity anomalies beneath fast-spreading ridges are parallel to the ridge. The differences between amplitudes of gravity anomalies indicate either variations in crustal thickness, or the presence of focused hot uprising mantle beneath slow-spreading ridges or along the ridge axis in the case of fast-spreading ridges. Slow-spreading ridges near hot spots

(e.g., Reykjanes ridge near Iceland) may have characteristics similar to fast-spreading ridges. This indicates that mantle temperature can also control the physical parameters of divergent boundaries.

Convergent Boundaries

A convergent plate boundary forms when a lithospheric plate, denser than the mantle, slides (subducts) beneath another plate. The oceanic lithosphere plunges beneath other oceanic lithosphere or beneath a continent. When two continents collide, some continental lithosphere may subduct and a mountain range is built (e.g., Himalaya). Broad and almost continuous zones of shallow seismicity, ductile deformation, and metamorphism characterize such zones. The distributed deformation of continents is due to the relatively low strength and low density of continental crust. Subduction zones are characterized by strong and localized seismic activity located within the plunging slab. Friction at the top of the plate causes earthquakes to form the so-called

Plate Tectonics,

Fig. 2 Ideal cross sections of: (a) slow-spreading ridge showing discontinuous small magma chambers (in violet) producing discontinuous oceanic crust (serpentinites in light blue containing gabbroic pockets in dark blue) and (b) fast-spreading ridge showing magma chamber, crystal mush (in violet), and magma sills and lenses (in black) producing a gabbroic (dark blue), sheeted dykes (white), and basaltic (dark green) crust. Flow directions and lithosphere/asthenosphere boundary are indicated in both diagrams (After Pomerol et al. 2005)

Wadati-Benioff zone. Intraplate compressional and extensional focal mechanisms are the responses to stresses generated by the subducting plate. This plate is separated from the overriding plate by deep trenches filled mainly by turbiditic sediments, pelagic sediments, cherts, and fragments of oceanic lithosphere that are internally imbricated in tectonic slices to form an accretionary prism.

Partial melting of the mantle overlying the subducting plate produces calc-alkaline magmas. Those magmas migrate upward and form archipelagos called volcanic arcs (chains of volcanic islands parallel to the subduction zone, f.i.: the “ring of fire” around the Pacific ocean). Two types of volcanic arcs are generally recognized: oceanic (island) arcs are formed by subduction of oceanic plate under another oceanic plate; continental magmatic arcs are formed by subduction of

oceanic plate underneath the continent. Arc magma forms when fluids expelled from the subducting slab (pore fluids at shallow depth or metamorphic dehydration of altered oceanic crust at greater depth) induce partial melting of the overlying mantle (the so-called mantle wedge). The magmas of continental arcs exhibit a wide range of calc-alkaline compositions (andesite and diorite, dacite and granodiorite, rhyolite and granite) due to fractional crystallization, continental contamination, and magma mixing in superposed magma chambers.

The distance of island arc volcanism from the trench is dictated by the inclination of the subduction zone, because appropriate temperature-pressure conditions for flux-induced melting occur at the same depth (about 100 km). Continental magmatic arcs are sites of high-temperature, low-pressure metamorphism, and

extensive crustal melting due to advection of heat by continuously intruding magmas.

Two types of subduction have been distinguished, depending on the age of the subducting lithosphere: (a) old, cold, and dense slabs subduct at a high angle or dip (e.g., Mariana subduction); and (b) young, hot, and less dense slabs subduct at a low angle (e.g., Chile subduction) (Fig. 3, from Internet). Mariana-type subduction exhibits deep trenches, short arc-trench distances, deep seismic activity (down to 670 km), and low-magnitude shallow seismicity indicating decoupling between the subducting and overriding plates. Retreat of the subducted plate and accompanying mantle flow (called “roll-over”) induces an extension in back-arc basins with eventual creation of new oceanic crust. Chile-type subduction is characterized as a seismic activity which does not exceed 200 km depth, shallow trenches, and long distance between the trench and the volcanic arc. The shallow inverse seismic activity is of high magnitude, indicating a high friction between the two plates that induces arc and back-arc compression.

Subduction zones are the sites of high-pressure, low-temperature metamorphism that develops at the base of the sedimentary prism and within the subduction channel. Thermal modeling shows variable depression of isotherms depending on the age of the lithosphere and rate of subduction. The subducting oceanic crust is metamorphosed progressively from blueschist (low-temperature, moderate-pressure) to eclogite (moderate-temperature, high-pressure) facies. Phase transformations within the subducting lithosphere induce intraplate seismicity and a large increase of density (by the transformation in eclogite of the subducting crust) which provides a major driving force for subduction.

Seismic tomography (two- or three-dimensional imaging of the Earth’s interior) shows that high-seismic-velocity, cold mantle from the subducting plate accumulates at the 670-km discontinuity when Mariana-type (steep-dip) subduction occurs. Tomographic imagery shows that cold material sinks episodically into the lower mantle, in some cases down to the core-mantle boundary.

Fig. 3 Two principal
architectures of Pacific
subduction zones

Transform Boundaries

A transform boundary (also known as conservative plate boundary) separates plates that move parallel to one another with no convergence and divergence, thereby conserving the areas of adjacent plates. The San Andreas Fault (California) or the North- and East-Anatolian faults (Turkey) and the Levant fault (Middle East) are good examples. These boundaries penetrate most of the lithosphere and generally are long-lived structures. They form deep valleys and pull-apart basins at the surface of the Earth. Transform boundaries link other plate boundaries, and can thus “transform” one type of tectonic boundary to another (e.g., from divergent to convergent boundary). Therefore, the stresses generated along the transforms originate from the relative motion of the two plates. Seismic activity can be intense with high magnitude (up to 7).

Ophiolites

An ► **ophiolite** is a slice of oceanic crust and underlying mantle thrust onto a continent by a process called obduction. Obducted ophiolites represent on-land relicts of oceanic lithosphere that escaped the subduction processes. Investigation of these structures has contributed greatly to our understanding of processes at divergent boundaries and tectonic processes related to transform faults. Two types of ophiolites have been described (e.g., Beccaluva et al. 2004): “Tethyan complexes,” which comprise complete mantle and crustal sequences (cumulates, dykes and basalts with mid-ocean ridge or island arc affinities) and “Cordilleran complexes” comprising dismembered calc-alkaline arc volcanic and plutonic suites.

The movement of oceanic plates away from the ridge toward the trench is associated with the development of ocean floor stratigraphy which consists, from base to top, or oldest to youngest, of pillow lavas overlain by bedded cherts, deep ocean pelagic sediments, and finally clastic sediments of the accretionary wedge. The interpretation of ocean floor stratigraphy has influenced significantly our understanding of the structure and age of oceanic lithosphere preserved in ophiolite sequences and accretionary orogens.

Hot Spots

Hot Spots are alignments of fossil to recent volcanoes (e.g., Hawaii and Louisville in the Pacific; La Réunion and Kerguelen in the Indian Ocean; Iceland, Azores, and Tristan da Cunha in the Atlantic Ocean) produced by the passage of a plate over a mantle plume (Fig. 4; position of hot spots from Westphal et al. 2002). These alignments of volcanic chains may exhibit a correlation between the age of the volcanoes and the distance from the active mantle plume. The duration of hot spot tracks varies from negligible to 90 Ma. Active volcanoes on the axis of the mantle plume can be situated near or on divergent plate boundaries, like Iceland on the Atlantic Ridge. Hot spots located near divergent plate boundaries influence the bathymetry and basalt chemistry for distances up to 800 km along the ridge axis. Large hot spots like Hawaii are situated over up-doming or swelling (100 km) of the lithosphere. The Polynesian Archipelagoes in the central Pacific are made up of numerous hot spot volcanoes and overlie a large positive 1,000-km-wide bulge called a “superswell.” Analysis of the main hot spot tracks leads to the conclusion that the deep-mantle source hot spots are fixed or move slowly relative to plate velocities. Tomographic images show that low seismic velocity hot mantle columns exist beneath hot spots and in some cases extend down to the core-mantle boundary, suggesting that mantle plumes may originate in the D'' seismic layer. These observations are at the origin of the mantle-plume concept.

Driving Forces of Plate Tectonics

It is generally accepted that plates move because of variations in the density of oceanic lithosphere and the weakness of the asthenosphere. Since more than 50 years, it is acknowledged that dissipation of heat from the mantle drives convection and implicitly also plate tectonics. Modern geophysical methods based on seismic tomography show large lateral variations in density throughout the mantle. These density variations are due in part to differences in rock chemistry and mineral structure, but mainly to changes of temperature that lead to the upwelling of hot regions and the

Plate Tectonics, Fig. 4 Position of recent hot spots. The diameter of *black circles* is proportional to the quantity of erupted magma

descent of cold regions. It is not entirely understood how plate tectonics is related to these motions. A major problem addressed by researchers since the 1960s is whether the driving force of plate tectonics is the mantle convection and/or the activity of mantle plumes, or whether plate tectonics is driven by surface boundary and plate forces such as slab pull and ridge push (see Gravitational Forces; Forsyth and Uyeda 1975). Any valid model has to reproduce the rigid behavior of plates, provide enough energy to produce stresses at the limits of plates, and produce continuous plate motion. Currently, two main types of forces are thought to drive plate tectonics: the friction (localized forces) and gravity (distributed forces) (Fig. 5, driving forces).

Frictional Forces

Basal drag results from friction between the asthenosphere and the lithosphere. It is supposed that the convection movement is transmitted through the asthenosphere and drags the overlying lithosphere. Trench suction occurs in subduction zones where the convection currents exert a

frictional pull on the subducting plate. This force results from small-scale convection in the mantle wedge which is driven by a subducting plate.

Gravitational Forces

Gravitational sliding (ridge push) is a distributed gravitational force produced by the higher elevation of oceanic plates due to upwelling of hot material at spreading ridges. Newly formed oceanic lithosphere at mid-ocean ridges is less dense than the underlying asthenosphere, but as the oceanic lithosphere moves away from the ridge it becomes colder, denser, and thicker (McKenzie 1969). Ridge push can be considered as a body force because the increasing thickness of the cold oceanic lithosphere creates a horizontal pressure gradient. However, lithosphere older than 90 Ma undergoes no further cooling and therefore does not contribute to ridge push. In other words, ridge push can be also regarded as a boundary force generated by the upwelling of young warm mantle beneath the ridge crest which causes a topography-driven horizontal pressure gradient that acts at the edge of lithospheric plate. If a hot

Plate Tectonics, Fig. 5 Schematic diagram for tectonic plate forces

spot is positioned at the spreading ridge axis, ridge push is amplified at least by a factor two (Ziegler 1993).

Slab pull results from the weight of the cold and dense subducting lithosphere. This force is dependent on the angle, age, and volume of this lithosphere, as well as the length of the trench (Chapple and Tullis 1977). The lateral distribution of dense and light masses deduced from seismic tomography led Davies (Vigny et al. 1991) to propose a model in which the excess density of the oceanic lithosphere in subduction zones is the most powerful source of plate motion. This hypothesis is supported by studies that show a positive correlation between plate velocities and age of subducting lithosphere. Collisional resistance, a force produced in high-viscosity ductile upper mantle material, is related to slab pull force.

Even if the slab pull is the most important force, it cannot be the only plate tectonic force, because some plates move without subducting boundaries, and other forces like basal drag are locally important. Therefore, plate movement results from the sum of forces acting upon the plate. A significant observation is that lithospheric plates attached to downgoing (subducting) plates move much faster than plates without subducting boundaries. The Pacific plate, which is surrounded by subduction zones, moves much faster than the plates of the Atlantic basin, which are continuous with the flanking continents.

Crustal Growth and Continental Construction

On the modern Earth, continental crust is created mainly at subduction zones. Here, release of aqueous fluid from dehydrating oceanic crust causes melting in the mantle wedge and generates the calc-alkaline magmas that evolve into granitoid continental crust. In other words, on the modern Earth, the formation of continental crust is linked directly to plate tectonics.

Two distinct processes are grouped under the term “continent growth.” To a geochemist or petrologist, it refers to the transfer of silicate material from the mantle into the continental crust. To a geodynamicist, the term refers to the construction of a continent, the process that assembles crustal segments of various types, compositions, and origins. This process combines the lateral accretion of island arcs, oceanic crust and oceanic plateaux, and microcontinents, with magmatic addition at convergent margins, to build a continent or ► [supercontinent](#). The term “continental crustal growth” or simply “crustal growth” is used for the first process and “continent construction” for the second.

The sites of both crustal growth and continent construction coincide with major accretionary orogens. The accretionary orogens comprise: (1) accretionary wedges, containing material accreted from the downgoing plate and eroded from the upper plate; (2) island arcs, back-arcs, dismembered ophiolites, oceanic plateaux, and old continental blocks; (3) post-accretion granitic rocks and metamorphic products up to the

granulite facies, exhumed high- or ultrahigh-pressure metamorphic rocks, and clastic sedimentary basins (e.g., Cawood et al. 2009). The concept of accretionary orogens is associated with the discovery of ocean-floor stratigraphy.

Crustal growth is linked directly to subduction and thus to the formation of oceanic lithosphere at spreading centers: if sea-floor spreading is a continuous process, continental crustal growth should also be continuous. According to many authors, the assembly of continents was an episodic process superimposed on quasi-continuous growth of the continental crust, at least through most of the Phanerozoic. The continental construction processes are commonly associated with large-scale plate reorganization that results from changes in the kinematics of plate motion and/or with superplume activity, which may account for the episodic character of lateral accretion (Vaughan and Searrow 2003). The fundamental cause of episodes of accelerated growth and construction of the continents can probably be related to changes in the activity of the mantle.

Mantle Convection

Mantle convection has been invoked as a fundamental process controlling plate tectonics (Davies 1999). Heat loss at the surface of the Earth and

calculations of heat dissipation in the mantle show that convection is an effective means of evacuating heat from the Earth's interior.

Experiments show that the mantle flows as a solid through two principal deformation mechanisms: diffusion and dislocation creep. The experimental laws of crystal deformation show that the mantle viscosity is a function of activation energy (activation enthalpy and volume), pressure, temperature, and differential stress. Many authors accept that diffusion creep is the major deformation mechanism in the mantle, in which case the viscosity is almost a linear function of depth, except at boundary layers (phase transitions). Reference viscosities of the upper mantle have been estimated using isostatic glacial rebound and subduction zone geoids. Viscosities of the order of 10^{20} Pa s are estimated for the asthenosphere and 10^{21} Pa s for the lower mantle.

The accepted model today describes the internal movement in the mantle as follows: active plunging of cold material in subduction zones, hot uprising mantle currents beneath hot spots, and discontinuous narrow passive upwelling of hot mantle beneath the ocean ridges (Fig. 6; from Westphal et al. 2002). Whether convection occurs in one cell or two depends on the properties at the 670 km depth discontinuity (Brunet and

Plate Tectonics, Fig. 6 Schematic cross section of the Earth showing cold subducting plates down to D'' layer and upwelling mantle plumes from D'' layer

Machetel 1998). This limit corresponds to a phase transition (spinel-perovskite) which corresponds to a downward increase of density of 0.4 g cm^{-3} , or about 10%. This density change is greater than the density difference between a cold plunging slab and the surrounding mantle, which means that the slab does not penetrate the discontinuity until all the phases have been transformed.

History

Plate tectonics is the paradigmatic theory of the modern geology since 40 years. It established that the major features of the Earth's surface depend on the dynamics of lithospheric plates, created from the ► mantle at the oceanic ridges and absorbed into the mantle at the oceanic trenches, except continental crust that can never sink and, thus, is condemned to be recycled in new mountain ranges. If moving plates are clear scientific evidence today, it was not at the beginning of the twentieth century when German meteorologist and geophysicist Alfred Wegener proposed his theory of continental translation (later translated with derisive sense in continental drift) against the leading theory on mountain formation.

In 1912, Alfred Wegener (1880–1930) proposed to consider that all continents might once have formed a single continent (today called a supercontinent) he named Pangea that might have been broken. Then, these continental masses might have drifted over oceanic crust. Their front margins (like a ship's bow), compressed and folded by the resistance of the ocean floor, might have formed mountain ranges (like Andes or the Rocky Mountains), and on the opposite, fragments of continents might have been detached in their wake as string of islands. Continents and ocean basins would not be permanent features of the Earth. Horizontal motions were more important than vertical motions defended by the theory of a cooling earth.

The model of mountains by contraction of a cooling Earth was suggested and developed in France by geologist Léonce Elie de Beaumont (1829) and defended in Great Britain by Henry De la Bêche. It found its best formalization at the end of the century in the work of the Austrian geologist Eduard Suess. According to Suess's theory, vertical motions of its crust explained the features of the Earth. As the globe cooled and began to sink, outer crust collapsed creating ocean basins and continents. Successive collapses changed the face of the Earth: ocean basins elevated into continents and continents collapsed to form ocean basins. Suess's theory was centered on "the breaking up of terrestrial globe." But this

model of "the shriveling apple" could not explain longer the compression rate calculated to unfold folding strata of the Alps or of the Himalayas. In the Alps, the horizontal extent of strata has been shortened to one quarter to one eighth of its original length, which would have required a shrinking of the circumference of the Earth by 3%, which means that Earth has cooled of about 2,400 °C.

At the end of the nineteenth century, geological views of Eduard Suess and of the European geologists were not shared by the American scientific community, which widely accepted the "permanence theory" developed by James Hall and James Dana. Oceans and continents were permanent features of the Earth's surface and change confined to limited areas on continental margins (*geosyncline*).

Wegener broke up with the secular cooling theory, collapsed by the discovery of natural radioactivity in 1896, and the assumption of a heating Earth. In contrast, he used the theory of isostasy, suggested by John H. Pratt and George B. Airy and named by Clarence E. Dutton in 1892, to interpret the Earth's crust in two layers. A light continental crust would float and drift on heavy oceanic crust and would never sink. The horizontal motions and deformations of the continents would cause the major geological features. Wegener's theory tried to unify data from paleontology, biogeography, geophysics, stratigraphy, geological mapping, and paleoclimatology to propose a synthetic model. He tried to unify European and American opposite views. The explanation of the rejection of his continental drift by most of the geologists of the 1920s and 1930s is complex and could not be justified only by the lack of a causal explanation of drift. The death of Wegener in 1930 and the inability to prove or disprove his theory closed the controversy. Debate was put aside in spite of the causal models proposed in the end of the 1920s by the Canadian geologist Reginald Daly and the British geologist Arthur Holmes. Daly in *Our Mobile Earth* published in 1926 proposed a gravity sliding as drift mechanism. Holmes in his paper of 1929 about *Radioactivity and Earth movements* proposed subcrustal convection currents to evacuate heat from the interior of the Earth. He

proposed continental drift as consequence of thermal convection. But the question of continental drift was not settled.

Because of his studies about earthquake waves, Sir Harold Jeffreys was persuaded that the Earth possessed a considerable strength, incompatible with models of drifting continents. The transmission of seismic waves could be imagined only within a stiff Earth. The study of the earthquake of Kupa of October 8, 1909, allowed Serbian geophysicist Andrija Mohorovicic to bring to light a brutal acceleration of the speed of propagation of the waves toward 50 km deep and to establish a seismic boundary between the crust and the mantle. Five years later, German seismologist Beno Gutenberg determined a major discontinuity at the depth of 2,900 km: the seismic boundary between mantle and core was discovered. In the 1920s, Gutenberg, through his works about deep-focus earthquakes and identification of a low-velocity zone, concluded to a weak crustal substrate and joined those who defended the possibility of subcrustal currents. In 1934, Gutenberg and an American seismologist Charles Francis Richter published new travel-time curves, which contributed to specify a seismic model of the globe. The discovery of an inner core's discontinuity by Inge Lehman, in 1936, and its interpretation by Beno Gutenberg and Richter as a separation between a fluid outer core and a solid inner core conducted in few years to establish a structural model of Earth's interior. The model of Harold Jeffreys and Keith E. Bullen little changed since 1940. In the 1950s, David Griggs, Harry Hess, and Félix Venig-Meinesz proposed convection models. Like that of Arthur Holmes, their models offered finally a physical reliable cause to the drifting continents of Wegener.

After the Second World War, the development of paleomagnetic studies was going to shake the trust in the continental permanence and revive the idea of drifting continents. The work of Bernard Brunhes in the early 1900s showed that old basaltic lavas are magnetized in directions making sometimes large angles with the present Earth's magnetic field. Basalt acquires its magnetization from the geomagnetic field when it crystallizes and passes under the Curie point of their magnetic

minerals (580 °C for magnetite). Considering that the mean geomagnetic field can be compared with an axial dipole situated at the Earth's center, the magnetic field's characteristics, recorded in the rocks, should be those of their geographic localization. Patrick Blackett, Stanley K. Runcorn, Edward Irving, and K. Creer, by the mid-1950s, observed that the geographic North Pole fossilized in lavas changed with geological time. The angle of polar difference increasing with time, a migration either of the poles or of the continents was clearly suggested. Wegener's hypothesis of polar wandering based on paleoclimatic data seemed to be confirmed. Polar wandering paths were determined for North America and Europe by Stanley Runcorn. A systematic difference appeared between the polar wanders of the two continents since the Triassic. But putting side by side North America and Europe, it disappeared. Paleomagnetic arguments strongly supported the idea of moving continents and the possibility of existence of supercontinents in the past, as Pangea, the old supercontinent imagined by Wegener, 30 years ahead. In the beginning of 1950, the American geologist Harry Hess used a magnetometer to record magnetic variations across the ocean floor. These magnetic variations are associated with the magnetite contained in oceanic basalts, which records the orientation and intensity of the Earth's magnetic field at the time of basalt extrusion. In the 1960s, magnetic studies revealed the existence of alternating stripes of normal and reverse polarity, which are symmetrically distributed on either side of the mid-ocean ridge. The alternation of direct and inverse magnetic polarity is related to periodic changes in the polarity of the Earth's magnetic field, which is recorded in the basaltic rocks. The marine geologists and geophysicists Frederick Vine and Drummond Matthews suggested in 1963 that the ► [mid-ocean ridges](#) mark structurally weak zones where the ocean floor was split in two along the ridge crest. It was suggested that pulses of magma rise along the ridge and create new oceanic crust, which then migrate laterally away from the ridge – the process called seafloor spreading. The explanation of the magnetic striping led to the rapid

acceptance of seafloor spreading as a key element of plate tectonics theory.

In the 1950s, geological and geophysical oceanographic explorations established a new physiography of the ocean floors. The ocean floor showed a world embracing mid-oceanic ridge system, cut by transverse faults, showed arc-trench system with extinct and active volcanoes, and revealed numerous seamounts, interpreted by Harry H. Hess as subsiding volcanoes. In 1959, Bruce Heezen, Marie Tharp, and Maurice Ewing published the first detailed bathymetric map of the North Atlantic Ocean. Campaigns of coring deep-sea sediment and dredging of rock samples from exposed scarps on the oceanic ridges revealed a great petrographic homogeneity of the seafloor (only basic and ultrabasic rock types) and lack of sedimentary rocks older than Cretaceous. In 1961, Robert S. Dietz expressed his hypothesis of a seafloor spreading, and a year later, Harry Hess, independently, published a paper where he proposed equally that the seafloor was created at mid-ocean ridges, then spread out toward the trenches where it sank into the mantle, driven by convection currents of the mantle. Canadian geophysicist Tuzo Wilson, studying transverse faults of the ridges, suggested in 1965 that they would limit several large, rigid crust areas that he called *plates*. The Earth's surface would be divided into plates limited by ocean ridges, ocean trenches, and transverse faults (such as the St Andreas fault in California) that would transform the one to the other one. Earthquakes and volcanic activity would characterize plate boundaries. In his model, the oceans are created, grow, and disappear; and the continents are fragmented, separated, and reassembled in what are now called "Wilson cycles." But Earth's crust was too thin to be stiff enough and required to extend about 100 km down that meant to the low-velocity zone of the mantle. Plates are lithospheric ones composed of what is called crust and the upper, rigid part of the mantle, the so-called lithospheric mantle. Further understanding of plate kinematics came from the work of the geophysicists William Jason Morgan and Dan McKenzie, who explained in 1968 relative displacements of adjacent plates. He showed that the movements

are parallel to transform faults and centered on a pole of rotation (the Euler pole) and that variations of seafloor expansion are a function of the distance from the pole of rotation. Using Jason Morgan's model of plates and Euler's theorem about translation of an area on a sphere, French geophysicist Xavier Le Pichon proposed the same year to divide Earth's surface into six major plates. Plate tectonics break with continental drift, because if continents move, they do not drift over ocean.

Geological aspects of the theory of plate tectonics were developed by the geologists John Dewey and John Bird, who showed in 1970 that the structure of active continental margins is dependent on the geometry and kinematics of subduction zones. This seminal paper showed geologists how the orogenic belts are linked to movements of the oceanic lithosphere and explained the relationship between plate tectonics and both the complex 3D movements at continental margins and the magmatic and metamorphic processes of mountain building. In 1977, the submersible vehicle Alvin observed hydrothermal vents on the east pacific ridge. Geologists were looking for deep-sea hot springs, which they predicted to exist along rifts. They discovered them, and in the same time, they made a greater discovery: vents were jammed with animals. Plate tectonics gave a new breath to understand the early beginning of the life on our Earth.

The early establishment of the theory of plate tectonics in the 1960s represented a revolution in Earth sciences, like British paleontologist Anthony Hallam wrote in 1972. For the first time, data from all of the branches of Earth sciences gathered in a unifying theory, which could explain past and present geological time and can also predict what will happen in the future.

Plate, Lithospheric

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble,
France

Synonyms

[Tectonic plate](#)

Definition

A *lithospheric plate* is a large cohesive mass of oceanic or continental ▶ [lithosphere](#) which moves as a single element in the process of ▶ [plate tectonics](#). The outer layer of the solid Earth is composed of nine major lithospheric or tectonic plates and many minor plates. They are relatively rigid, and they float on and move atop the more deformable ▶ [asthenosphere](#) at speeds relative to each other varying from 2 to 10 cm/year. The largest, Pacific, plate is ~4000 km long and wide and up to 100 km thick. The upper part of the lithosphere plates may consist of either ▶ [oceanic](#) or of ▶ [continental crust](#) and is then called “continental” and “oceanic lithosphere,” respectively. Oceanic plates are created at ▶ [mid-ocean ridges](#) and are destroyed at subduction zones. The Pacific and Nazca plates and several smaller plates consist entirely of oceanic lithosphere, but the majority contain both continental and oceanic lithosphere. Because of thick roots beneath Archean cratons, the maximum thickness of continental plates reaches several hundred kilometers.

Platinum Group Elements

Nicholas Arndt
Emeritus Professor, ISTerre, University Grenoble
Alpes, Grenoble, France

Acronyms

PGE; PGM

Definition

The platinum group elements (PGE) or metals (PGM) – ruthenium (Ru), rhodium (Rh), palladium (Pd), osmium (Os), iridium (Ir), and platinum (Pt) – have similar chemical characteristics and behave as a group during geochemical processes. They are strongly siderophile (iron-loving) and chalcophile (sulfur-loving) and are therefore concentrated in the core of the Earth and in iron meteorites, in sulfide ore deposits, and to a much lesser extent in the Earth's mantle. An important geological application of the PGE is their use as tracer of meteoritic material, most famously Ir in the development of the meteorite impact hypothesis (▶ [Chicxulub Crater](#)), which caused the Cretaceous-Tertiary ▶ [mass extinction](#). The isotopic system rhenium-osmium is used to date mafic-ultramafic rocks, ore deposits, or some organic-rich sediments, and as tracer of processes in the Earth's mantle. The Os isotope ratio ($^{187}\text{Os}/^{188}\text{Os}$) is also used to trace changes in oceans through time, such as weathering flux. The occurrence of small excesses of PGE in the mantle has been often indicated as evidence of a

late contribution of chondritic material to the Earth (► [Late Veneer](#) hypothesis). In some environments, PGE can also indicate anthropogenic effects such as the use of catalytic converters in cars.

[PLANetary Transits and Oscillations of stars](#)

Definition

PLATO 2.0 (PLANetary Transits and Oscillations of stars) is a mission for the detection and characterization (radius, mass, age) of transiting exoplanets at orbital distances up to the habitable zone of solar-like stars. In addition, PLATO 2.0 will study the stellar structure through asteroseismology.

Overview

PLATO 2.0 is the first space mission designed for the simultaneous search for transiting exoplanets and study of their host stars through

► [asteroseismology](#) (Rauer et al. 2014). Selected as the third mission of the cosmic vision science programme of ESA, it is planned for a launch in 2024, PLATO 2.0 will be developed in a partnership between ► [ESA](#) (providing the spacecraft, launch, and elements of the operation) and a scientific consortium (providing the payload, including the telescopes, elements of the operations, and scientific planning), led by Germany (DLR) and consisting of elements from essentially all of the ESA member states.

Basic Methodology

When an exoplanet travels between its host star and the Earth, it induces a weak drop of the star's brightness (a mini eclipse). The detection of this periodic ► [transit](#) in the star's light curve, together with its careful analysis (e.g., discerning the transit signature from, e.g., star spots), reveals the existence of the exoplanet and provides important characteristics such as the planet's radius, its orbit parameters, and the rotation period of the star. By also studying the properties of the star, such as its radial velocity, its radius, and its age, the absolute values of the mass, radius, and age of the planet can be determined.

Stars, acted on by gravity, pressure, and Coriolis forces, behave as oscillators with many specific modes. These oscillations are detectable through tiny variations in the stellar brightness, and their analysis provides important parameters on the stars' internal structure. Most importantly, parameters such as mass, radius, and age can be determined with significantly higher precision in this way than with classical methods such as spectroscopy.

If the stellar parameters of the planet's host star have been determined through asteroseismology, the planetary values can be determined with unprecedented accuracy.

PLATO 2.0 is designed to have an ultrawide field of 2250 square degrees that enables it to monitor the flux from hundreds of thousands of stars for uninterrupted periods of up to several years. This allows users of the spacecraft to detect and measure the tiny variations in the stellar flux that are caused either by stellar activity, stellar internal oscillations, and/or the possible transit

signature of an orbiting exoplanet. The satellite carries thirty-four (34) six-lens visible telescopes each with a clear aperture of 12 cm and each focusing the stars' light on an individual focal unit hosting four frame-transfer ► [CCD](#) matrices of 4510×4510 18 Micron Pixels. The detectors, whose temperature is cooled passively, have a high quantum efficiency in the visible wavelengths. Each telescope is equipped with an individual baffle to reduce the parasitic straylight, as well as the whole assemblage being sheltered by an efficient sun shield. In order to remain shielded from the scattered Sunlight, as the satellite travels around the Sun in its L2 Lissajou (Lagrange points) orbit, it is necessary to rotate the spacecraft 90° around its optical axis every 90 days. Thirty-two of the telescopes (referred to as "normal cameras") observe with a cadence of 25s and monitor objects fainter than visual magnitude 8. The two remaining telescopes (referred to as "fast cameras"), equipped with colored filters, observe with a cadence of 2.5s and observe stars between visual magnitudes 4 and 8.

Key Research Objectives

Exoplanets and Asteroseismology

PLATO 2.0 will monitor about 1,000,000 solar-like stars, during periods of between a few months and ~ 3 years, searching for the signature of the transit of a planet with the same size as the Earth.

While PLATO 2.0 will be able to detect quite easily super-Earths in short (less than 2 months) orbits, its major breakthrough will be for planets down to Earth size orbiting within the habitable zone (HZ) of large numbers of solar-like stars (which requires the detection capability of periods larger than approximately 6 months). This is a parameter range not explored by any past, current, or planned space mission.

PLATO 2.0 will determine albedo and atmospheric properties for a large number of objects by performing the bulk observation of secondary transits (Alonso et al. [2009a, b](#)), as well as by measuring the changes in illumination of exoplanets as their phases change.

For about 85,000 bright stars with magnitudes smaller than 11.3, the stellar light curve will be

recovered with a precision accurate enough to obtain the mass and size of the star with an error of a few percent through asteroseismology. This will allow the detailed characterization of any planet found orbiting those stars. Their ages will also be determined with unprecedented precision ($\sim 10\%$) and with information about orbital distributions, and from some of the atmospheric parameters we will get the first information about the evolution of exoplanets.

PLATO 2.0 and Stellar Physics

Through asteroseismology solar-like stars, stars hotter than the Sun, and red giants can be studied in detail through solar-like oscillations. Data from the CoRoT and Kepler space missions have demonstrated that the much more capable PLATO 2.0 will be able to open a new chapter in stellar physics, as well as carry out detailed galactic archeology for our part of the Milky Way galaxy.

Applications

PLATO 2.0 will be the next order-of-magnitude step, beyond CoRoT (Baglin et al. [2007](#)), Kepler (Basri et al. [2005](#)), ► [TESS](#), and ► [CHEOPS](#), in our search for exoplanets, enabling us to further our understanding of the distribution of sizes and masses of large numbers of small and "rocky" planets. This will enable progress in theories for the formation and evolution of stellar systems and also their host stars. The improvement in physical parameters of large numbers and kinds of stars will allow stellar physics to evolve and will impact on large areas of astrophysics.

PLATO 2.0 will bring together the European exoplanetary community and drive the evolution of ground-based follow-up which will itself impact many areas.

Future Directions

PLATO 2.0, together with the preceeding missions TESS and CHEOPS, will constitute the main steps in preparing for the spectroscopic missions that will follow. ► [JWST](#) will of course carry out spectroscopy at roughly the same time as PLATO 2.0, but it is equipped with only

simple coronagraphic capability. PLATO 2.0 results will map out the direction that the astronomical community will have to move toward in order to make progress in the search for extraterrestrial life.

Plurality of Worlds

Florence Raulin-Cerceau
Maître de Conférences, Centre Alexandre Koyré
(UMR 8560-CNRS/EHESS/MNHN/CSI)
Muséum National d'Histoire Naturelle, Paris,
France

The plurality of worlds, regarded as other inhabited worlds in the universe, is a debated question since Antiquity. The Greek philosopher Anaximander considered that countless worlds succeeding one another could be born from an infinite universe. The atomist Democritus, as well as Epicurus and later Lucretius, maintained that worlds in infinite number have emerged from atoms and infinite void, a materialistic view of the universe. Following the heliocentric Copernican theory, new speculations were formulated. Inquisition rejected the infinity of worlds proposed by

the dissident Dominican friar Giordano Bruno. However, famous personalities expounded this idea (Kepler, Huygens, Fontenelle) which finally became a scientific topic during the nineteenth century (Flammarion, Proctor). Astrobiology revisits today this concept through space exploration and the continuous discoveries of exoplanets.

Definition

Pluto (formal designation: 134340 Pluto) is the largest known object of the Kuiper belt, a ring of bodies beyond the orbit of Neptune. From its discovery in 1930 to 2006, it was considered the solar system's ninth planet. However, the International Astronomical Union's (IAU) reclassification of solar system objects in 2006 puts Pluto in the category of dwarf planets, that is, objects large enough to satisfy the condition of

hydrostatic equilibrium but that do not dynamically dominate their surrounding population. Pluto has been visited for the first time by the New Horizons spacecraft during a flyby on July 14, 2015, which allowed for detailed observations of its surface, atmosphere, and moons.

History

Pluto was discovered on February 18, 1930, by a 23-year-old farmer and amateur astronomer Clyde Tombaugh. Tombaugh was employed at Lowell Observatory with the task of searching for a putative massive (several Earth masses) object, known as “planet X.” Planet X had been predicted by Percival Lowell (and independently by others) on the basis of analyses of Uranus’ motion, in much the same manner Neptune had been discovered in 1846. After about 1 year of search, Tombaugh spotted a moving object on plates recorded on January 23 and 28, 1930. The discovery was announced on March 13 (for the 75th anniversary of Lowell’s birth) in the form of an observation circular cautiously entitled “The Discovery of a Solar System Body Apparently Trans-Neptunian.” Inspection of archive observations of the world’s major observatories confirmed the detection of the object on no less than 136 plates, the earliest of these “prediscovery” images dating from January 1914. This allowed an accurate orbit to be quickly established, confirming that the object, then at 41.3 AU from the Sun, was indeed trans-Neptunian. However, Pluto was immediately realized not to be the object that was looked for. With its faint magnitude (about 15 at discovery) and unresolved appearance, Pluto must have been very small. Initial estimates showed it to be less massive than the Earth (and measurements in subsequent decades only aggravated the problem), indicating that the new object was unable to perturb the motion of Uranus. Tombaugh continued his quest of Planet X for another 10 years, without success. The mystery was not solved until 1993, when updated calculations of Uranus’ motion, using the accurate mass of Neptune provided by Voyager 2, made the perturbations vanish, and with them the need for a planet.

Overview

Mass, Size, and Internal Structure

Pluto’s radius is 1188.3 ± 1.6 km and its mass is $1.303 \pm 0.003 \times 10^{22}$ kg, which is 0.22% that of Earth. Its surface area is about 17.7 million km² (equivalent to the surface area of Russia). Its surface gravity is 0.62 m/s², which is about 1/15th of the surface gravity on Earth. Pluto is smaller and less massive than seven moons of the solar system: Ganymede, Titan, Callisto, Io, the Moon, Europa, and Triton. However, Pluto may be the largest object in the Kuiper Belt (dwarf planet Eris approximate radius is 1163 km) and the second-most massive after Eris.

Based on its mass and size, Pluto’s density is 1.860 ± 0.013 g/cm³. The interior of Pluto is thought to be differentiated, with rocky material having settled into a dense silicate core (corresponding to two-third of Pluto’s radius) surrounded by a mantle of water ice (one-third of Pluto’s radius). It is possible that heating produced by the decay of radioactive elements continues today, creating a subsurface ocean of liquid water 100–180 km thick at the core–mantle boundary. Many modeling studies support the presence of a past or still existing subsurface ocean.

Pluto has no magnetic field.

Orbital and Spin Parameters

Orbit

With a semimajor axis of 39.5 AU, Pluto orbits the Sun in a mean 248.1-year period. Its highly elliptical (eccentricity = 0.249) and inclined ($i = 17.1^\circ$ over the ecliptic) orbit is distinctly different from those of the planets. The large eccentricity brings Pluto to 29.7 AU from the Sun at perihelion (lastly on September 5, 1989) and 49.7 AU at aphelion, which leads to the normal incident solar flux varying by a factor of ~ 3 over the course of its orbit. Pluto is therefore occasionally closer to the Sun than Neptune (lastly between February 1979 and February 1999), but the inclination of Pluto’s orbit is such that the two orbits do not intersect; when Pluto is near

perihelion, it is also far from the ecliptic plane. Moreover, Pluto and Neptune appear to be in 3:2 mean motion resonance, that is, for every two orbits that Pluto makes around the Sun, Neptune makes three (each cycle lasts about 495 years). The consequence of this synchronism is that the minimum distance between Pluto and Neptune is 17 AU. Ironically, Pluto can come closer to Uranus (12 AU). More fundamentally, these large distances imply that Pluto's orbit cannot be destabilized by the giant planets.

Pluto's orbit evolved over long timescales. First, its eccentricity oscillates between 0.222 and 0.266 with a 3.95 million years (Myr) period. Second, its argument of perihelion (the angle between the point where Pluto crosses the ecliptic and the perihelion) liberates by 24° with a period of 3.96 Myr. Third, the longitude of the ascending node (the point where Pluto crosses the ecliptic when passing from below to above the plane) is in near-resonance with the above liberation and regresses over 360° with a period of 3.7 Myr.

Computer simulations have predicted Pluto's orbital motion over the past and the next 10–20 million years, but beyond that timescale, calculations become speculative because of chaotic behavior.

Obliquity and Rotation

One day on Pluto lasts 6.387 Earth days, which is intermediate between fast rotators like Earth and Mars and slow rotators like Venus and Titan.

In Pluto's current orbit, the obliquity (angle between the planet's spin axis and its orbital axis) is 119.51° , equivalent to 60.49° in retrograde rotation. This high obliquity means that the annually averaged insolation is highest at the poles and lowest in the equatorial regions, in particular at 25°N and 25°S . Pluto's obliquity varies by about 23° between 104° and 127° over a period of 2.8 Myr. Consequently, over this timescale, the latitude of minimum insolation moves from $\pm 30^\circ$ to the equator, and the difference between the annually averaged insolation at the equator vs. the poles varies accordingly.

The reason for the high obliquity of Pluto could be related to a polar wander mechanism.

Satellite System

Pluto possesses five satellites, by order of increasing distance to Pluto: Charon, discovered in 1978 by J. Christy, Styx, Nix, Kerberos, and Hydra, detected over 2005–2012 in Hubble Space Telescope (HST) images. The five satellites lie in the equatorial plan of Pluto and have orbital periods of 6.387, 20.2, 24.9, 32.2, and 38.2 days, forming a 1:3:4:5:6 sequence of near (but not exact) mean motion resonances with Charon. Charon and Pluto form a remarkably "balanced" pair, with Charon's radius and mass being approximately one-half and one-eighth of Pluto's (606.0 ± 0.5 km, $1.586 \pm 0.015 \times 10^{21}$ kg, which is 12.2% of Pluto's mass). The barycenter of the Pluto–Charon system lies outside Pluto, justifying the use of the wording "binary system." Strictly speaking, Charon does not orbit Pluto; rather, the two bodies orbit their common barycenter. The system is also unusual among planetary systems in that each body is tidally locked to the other, which means that the period of mutual revolution is exactly equal to Pluto's and Charon's rotation periods, with each body having the same hemisphere facing the other. This synchronous motion is the consequence of mutual tidal forces.

The other four moons are not spherical (but instead elongated) and their dimensions are $16 \times 9 \times 8$ km, $49.8 \times 33.2 \times 31.1$ km, $19 \times 10 \times 9$ km, and $50.9 \times 36.1 \times 30.9$ km for Styx, Nix, Kerberos, and Hydra, respectively. They orbit the common barycenter rather than Pluto itself and are in stable dynamic resonances with Charon and with each other, with orbital periods close to a 3:4:5:6 ratio, respectively. These resonances may have been forced when Charon became tidally boosted into its current synchronous orbit. Unlike Charon, they are not in tidal lock with Pluto. Instead, they tumble chaotically. For instance, Hydra rotates 89 times on its axis for every orbital revolution.

Similar to the giant impact that formed the Earth's Moon, Pluto satellite system is thought to have resulted from a giant impact, that occurred early in the solar system history, between Pluto and a similar-sized body. The main clues are the

large masses of Pluto and Charon, the great specific angular momentum of the pair, and the coplanar system of the smaller satellites. After the collision, which may well have formed Charon intact, tidal forces over timescales of only a few tens of millions of years would have led to Charon's current circular and synchronous orbit. The collision also released material that consolidated into small moons in the Pluto–Charon orbit. However, it remains unclear what yields the large orbit distances of the moons and how they came to be near resonances with Charon.

Surface

Pre-New Horizons Knowledge

Pre-New Horizons Earth-based near-infrared spectroscopy indicated that Pluto's surface is covered by a variety of ices: volatiles N_2 , CO , CH_4 , with most of the CO and CH_4 occurring in dissolved form in N_2 , and non-volatile H_2O . Regions covered by essentially pure CH_4 were also evidenced. Charon's surface was found to be covered by H_2O ice, with possible evidence for ammonia hydrates. The bulk densities of Pluto and Charon were estimated to be 2.0 and 1.7, respectively, indicating a mixture of rocks and ices in approximately equal proportions.

Thermal measurements indicated that Pluto's surface temperature varies from ~ 37 K in the bright regions (temperature of the N_2 -rich ice) to ~ 60 K for the darkest areas when illuminated, with a low surface thermal inertia (~ 20 – 30 $J\ m^{-2}\ s^{-0.5}\ K^{-1}$ for the CH_4 -rich and volatile-free terrains). For pure N_2 , this implies that N_2 is in its β -crystalline phase with a temperature above the 35.62 K phase transition. The low thermal inertia implies a porous structure for the top few cm, which are affected by the diurnal temperature cycle.

Surface Appearance and Geology

The flyby of Pluto by New Horizons revealed a variegated surface, with a large number of surface features, brightnesses, and colors. New Horizons images also showed evidences of a complex geological history on Pluto's surface, with a

surprisingly pronounced topography, with 5-km deep depressions and 5-km high water-ice mountains, and a wide variety of geological landforms, including those resulting from glaciological and surface–atmosphere interactions as well as impact, tectonic, possible cryovolcanic, and mass-wasting processes.

The main prominent structure is Sputnik Planitia, a 1000 km-wide and several-km deep impact basin filled by a crater-free (and therefore geologically young, less than 10 Myr) ice sheet made of nitrogen ice, with traces of methane and carbon monoxide. The plains of the ice sheet display polygonal cells, suggested to be convective cells, obvious signs of glacial flows, sublimation pits, icy dunes, and wind streaks, thus hinting for significant surface–atmosphere interactions.

The largest dark feature on Pluto is Cthulhu Macula, located west of Sputnik Planitia at the equator. Its dark color results from the absence of exposed volatile ice and instead the accumulation of complex hydrocarbons, called tholins, onto the surface. These tholins possibly formed in the atmosphere from methane and nitrogen photolysis by solar ultraviolet light and cosmic rays. Cthulhu presents a large number of craters, which suggests that it may be billions of years old.

Normal reflectance of Pluto's surface ranges from 0.08 to 1.0, with the lowest values associated with the dark region of Cthulhu and the highest values to the bright volatile-covered Tombaugh Regio and the north pole. Pluto's mean Bond albedo is 0.72 ± 0.07 .

Surface Composition

New Horizons confirmed that most of Pluto's surface is covered by volatile N_2 , CH_4 , and CO ices in various mixtures. Less volatile methanol (CH_3OH) and hydrocarbon ices have been detected near the dark region of Cthulhu and are thought to be derived ultimately from both UV photochemistry and ion irradiation at Pluto's surface (see below). Non-volatile “bedrock” H_2O and NH_3 -hydrate ices were also detected on the surface. H_2O ice and ammoniated species dominate the surfaces of Charon and of the small moons. Molecular O_2 (abundant in the coma of comet 67P/Churyumov-Gerasimenko) and CO_2

ice (common on many icy satellites and abundant on Triton) were not detected.

Several processes could possibly have impacted Pluto's surface composition (and geology): cryovolcanism and tectonic activity over astronomical, darkening and contamination by haze sedimentation and by direct photolysis/radiolysis of the ices on seasonal or multi-seasonal timescales. The topography also impacts the volatile sublimation/condensation rates and therefore the ice distribution: N_2 favors low altitudes (e.g., Sputnik Planitia), whereas CH_4 favors high altitudes (e.g., Bladed Terrain, Pigafetta Montes, etc.).

Outside Sputnik Planitia, maps of surface composition (but also of albedo and color) show latitudinal banding, with non-volatile material dominating the equatorial region and volatile ices at mid- and polar latitudes. This pattern is driven by the seasonal cycle of insolation. The composition of terrains in the Sub-Charon hemisphere or south of $30^\circ S$ was not measured because these terrains were plunged into darkness (night-time and polar winter, respectively).

Atmosphere

Atmospheric Composition

Pluto's atmosphere is mainly N_2 , due to its high volatility and dominance on Pluto's surface, with minor amounts of methane (0.5%) and CO (0.05%), all in (quasi) solid–gas equilibrium with their ices on the surface. Methane is much less volatile than N_2 , and its relatively elevated abundance probably reflects sublimation from pure methane patches at Pluto's surface, that are warmer than N_2 ice, whose temperature is controlled by sublimation cooling.

In the upper atmosphere, solar ultraviolet radiations and cosmic X and gamma-rays drive N_2 and CH_4 destruction, yielding photochemical reactions that form more complex compounds in trace amounts (and not volatile at Pluto's surface temperatures), including ethane (C_2H_6), ethylene (C_2H_4), acetylene (C_2H_2), heavier hydrocarbons, and hydrogen cyanide (HCN).

Atmospheric Pressure

Since 1985, ground-based stellar occultation observations have indicated that Pluto's atmosphere is tenuous and time-variable. In particular, they showed that the atmospheric pressure increased by a factor ~ 2.5 between 1990 and 2015. In 2015, New Horizons measured a surface pressure of about 1.1 Pa in 2015, roughly 100,000 times less than Earth's atmospheric pressure. This value should be close to its annual maximum, according to models, due to seasonal effects, with regions covered by N_2 ice moving into summer and warming. The pressure should decrease during the next decades, with a minimum of a few mPa near aphelion. Larger variations can be expected during other obliquity or orbital conditions. Pluto's atmosphere is thick enough to be global, that is, the surface pressure and N_2 ice temperature are (except for topography) essentially independent of location on Pluto.

Atmospheric Haze

New Horizons also revealed a blue haze surrounding Pluto, structured in roughly 20 regularly spaced haze layers in the first 200 km above the surface. These 1–10 km thick layers could be the result of atmospheric waves, possibly generated by the volatile sublimation–condensation cycles or by air masses flowing over Pluto's mountains. The visible haze extends to ~ 600 km altitude.

The normal optical depth of the haze is estimated to be within 0.004–0.013. Different observations give different answers regarding haze particle sizes. Although the blue color points to particle radii near 10 nm, the ratio of brightnesses observed at different phase angles point to radii larger than 100 nm. These findings can be reconciled by invoking the aggregation of small (tens of nm) particles into larger (hundreds of nm) clusters, a situation already encountered on Titan.

The haze may consist of “tholin-type” solid particles, as on Titan. Their formation originates in the upper atmosphere, where N_2 , CH_4 , and CO are photolyzed by UV and cosmic high-energy radiation, leading to photochemical production of hydrocarbons (such as C_2H_2 , C_2H_4 , and C_2H_6) and nitriles (such as HCN) and then to the formation of these solid aerosols through

mechanisms of coagulation and aggregation. An alternative scenario suggests that the haze particles are mostly made of hydrocarbon ice (C_2H_4) that condenses on small tholin nuclei. Finally, there is no unambiguous evidence for condensation clouds in Pluto's atmosphere.

Atmospheric Temperatures

The Radio experiment (REX) on-board New Horizons measured a thermal profile consistent with those derived from Earth-based stellar occultations. REX showed a cold, dense layer in the lowest 3 km above the N_2 ice-covered surface in Sputnik Planitia, with a mean temperature (38.9 ± 2.1 K) close to the condensation temperature of N_2 . The cold layer is capped by a strong inversion with a peak gradient of $+9.5 \pm 1.2$ K km^{-1} (i.e., a stratosphere), mainly due to methane absorption. The temperature reaches its maximum at height 20–40 km (100–110 K) and then slowly decreases (about 0.2 K/km), reaching 70 K in the upper atmosphere (>400 km). Causes of this decrease are unclear, as the identified gases seem to provide insufficient cooling. It has been suggested that the organic haze has a significant radiative impact and is responsible for the cooling of the upper atmosphere but this remains to be explored in more details.

Atmospheric Escape

New Horizons detected the presence of atmospheric gases up to 1670 km altitude. Post-New Horizons models suggest that Pluto's atmosphere is currently (2015 conditions) losing only 1×10^{23} molecules of nitrogen and 5×10^{25} molecules of methane every second. Over the age of the solar system (~ 4.5 Gyrs), this corresponds to several centimeters of nitrogen ice and several tens of meters of methane ice lost to space. This may not be significant compared to the estimated reservoirs of nitrogen and methane ice on Pluto's surface. Nonetheless, Pluto's weakly escaping atmosphere may be at the source of Charon's poles' red coloration, interpreted as due to the capture of CH_4 gas escaping from Pluto and attendant condensation and chemical processing on Charon's cold poles.

Climatic Evolution

The climate of Pluto is a complex system in which the atmospheric dynamics are coupled with the N_2 cycle (sublimation and condensation processes induce surface pressure variations with time and control the winds) and the CH_4 and CO cycles (both partly control the radiative properties of the atmosphere and additionally CH_4 drives atmospheric photochemistry and haze formation). These cycles strongly depend on surface ice distribution and temperatures, themselves controlled by insolation changes and contamination by dark haze particles.

Changes in insolation and surface temperatures occur on diurnal, seasonal, and astronomical timescales. The astronomical timescale is dominated by changes in obliquity, solar longitude of perihelion, and eccentricity, also known as the Milankovitch mechanism, which also occurs on other planetary bodies such as the Earth, Mars, and Titan.

These variations force the volatile ices that form glaciers, frost, or lakes to migrate in different regions over time and causes meter-sized changes of their thickness. For instance, the N_2 -rich Sputnik Planitia ice sheet and the surrounding terrains exhibit numerous evidences of climate variation: active glacial flow on the edges of the sheet, icy dunes, fluvial features and ponds (that could have been shaped by liquid flows at the base of thick N_2 glaciers, now disappeared), deep sublimation pits, and erosions of water ice mountains. A variety of terrains outside Sputnik Planitia are also thought to have been carved by ancient glaciers. The major CH_4 deposits include the massive Bladed Terrain at the equator and several ice mantles at mid-northern latitudes. Climate models have been able to relate the formation of these geologic features to the Milankovitch parameters history of Pluto.

The atmosphere is also impacted by seasonal and long-term changes insolation. For instance, climate models have shown that surface pressure and atmospheric abundances of CH_4 and CO should have been minimal during very high obliquity periods ($\sim 104^\circ$, i.e., 76° in retrograde rotation) and maximal during low obliquity periods ($\sim 127^\circ$, i.e., 53° in retrograde rotation), with surface pressures remained in the range of 0.01 μbar

to 1 mbar and CH₄ atmospheric mixing ratio in the range of 0.001–10%. Higher pressures up to ~100 mbar (close to the triple point allowing liquid N₂ or CH₄ on the surface) have also been suggested but require extreme conditions including large and very dark volatile ice deposits covering Pluto's poles and low thermal inertia. These changes in surface pressure and trace gas abundance over time also impact photochemistry, haze and cloud amounts and composition, and therefore thermal structure and surface contamination.

Origin and Relation to Other Kuiper Belt Objects

Once thought to be an escaped satellite of Neptune (but we now know, it is impossible for Pluto to originate from a planet that it never approaches), the true place of Pluto in the solar system was revealed by the discovery of the Kuiper Belt from 1992 onward. Many resonant objects have been discovered (about 30% of the trans-Neptunian population); those located in the 3:2 resonance have been termed “Plutinos.” According to a popular model known as the “Nice model,” the overall structure of the Kuiper Belt results from mutual interactions between an initially massive and “cold” disk (i.e., bodies with low eccentricity and low inclination orbits) of planetesimals and the migrating giant planets. The initial Kuiper disk may have contained ~30 Earth masses and have harbored a thousand of Pluto-sized bodies. Neptune's outward migration may have involved a brief chaotic phase that expelled most of the planetesimals from the disk, leaving a Kuiper Belt of only ~0.03 Earth masses. Subsequent and gentler migration of Neptune would then have captured “cold” objects into mean motion resonances. While Pluto satellite system is particularly rich, multiple systems are common (~15%) in the Kuiper Belt.

Finally, it should be noted that, for both its atmosphere and surface, Pluto shows a clear similarity with Neptune's satellite Triton. Triton's atmosphere, as revealed by Voyager 2, is also very tenuous, nitrogen dominated with some traces of methane. Near-infrared spectra of Triton show that the ice composition, at its surface, is

very similar to that of Pluto. This goes along with dynamical arguments that indicate that Triton is a Kuiper Belt object captured by Neptune.

Definition

Peptide nucleic acid (PNA) is a DNA mimic that was first described in 1991. Although it is chemically remote from natural ▶ [nucleic acids](#) like DNA, being based on a pseudo peptide backbone

with pendant nucleobases, it is an effective structural DNA mimic capable of forming stable Watson-Crick sequence complementary duplexes with DNA, RNA, or itself. Furthermore, its chemical structure is uncharged, achiral, and based on “simple” chemistry being compatible with primordial (Earth and meteorite) conditions. Thus, it may be speculated that PNA type of (genetic) informational molecules could have preceded ► [RNA](#) in prebiotic evolution of life.

Overview

It is often hypothesized that our contemporary life based on DNA, RNA, and protein through the “central dogma” was preceded by a primordial life-form based solely on RNA being both the genetic material and providing enzymatic (catalytic) activity (the ► [“RNA world”](#)), and that this RNA world subsequently evolved into contemporary life by introduction of proteins and DNA. However, due to the very limited stability of RNA as well as lack of robust prebiotic synthesis routes for RNA precursors (in particular ► [ribose](#)), it is difficult to imagine how RNA molecules could have formed on the primitive Earth and how they would have survived long enough to allow creation of life. Thus, the idea of a pre-RNA life based on a more stable and prebiotically compatible genetic material has been entertained by many researchers. PNA is an example of one such material. It is extremely stable, precursors have been found in “prebiotic soup” experiments as well as in meteorites, and PNA is able to communicate genetic information with both RNA and DNA via Watson-Crick duplex formation. Furthermore, simple model experiments have demonstrated that chemical PNA replication as well as PNA to RNA transcription type processes may take place. So far, we are lacking evidence that a PNA world and a PNA to RNA world transition did take or even could have taken place at the early stages of the origin of life, but the data should encourage further experiments to investigate the (chemical) feasibility such a scenario. Indeed, a prerequisite for a

“PNA world” – in analogy to the RNA world hypothesis – would be the discovery of catalytically active PNA oligomers (“PNazymes”), which might have driven metabolic and replication life processes, and upon which evolutionary selection could have operated.

Polarized Electron

Jun-ichi Takahashi

Faculty of Engineering, Yokohama National University, Yokohama, Japan

Synonyms

[Spin-polarized electron beam](#)

Definition

Polarized electrons can be defined as an electron ensemble in which the average of the spin angular

momenta of the electrons is distributed in a specified direction (spin-polarized electrons). The typical spin-polarized electrons existing in nature are beta ray electrons from radioactivity decay of elements. The spin of electrons in beta rays is longitudinally polarized due to parity non-conservation in the weak interaction mediated by charged W particles.

In general, the helical behavior of energetic quantum beams can be characterized with “helicity,” that is, the spin angular momentum projection onto the kinetic momentum direction. The spin of beta ray electrons is polarized to the opposite direction of the beam propagation; that is, the helicity of beta electrons is $-1/2$. Expressing positive spin vector as a right-hand helix, positive helicity electrons correspond to right-handed and negative helicity to left-handed symmetries, by analogy to right- and left-handed circularly polarized light.

From the standpoint of astrobiology, one of the hypotheses for the origin of biomolecular chirality is called the “cosmic scenario.” In this scenario, asymmetric energy sources in space, such as beta rays, induced asymmetric chemical reactions of precursors in interstellar dust, resulting in the enantiomeric excess of terrestrial bioorganic compounds.

Polarized Light and Homochirality

Louis d’Hendecourt

Institut d’Astrophysique Spatiale, Université Paris-Sud 11, Orsay Cedex, France

Keywords

Circular dichroism · Enantioselectivity · Linearly and circularly polarized light · Optical activity

Definition

Natural light is composed of an oscillating electromagnetic field traveling in vacuum at a speed of c . It can thus be represented by a wave vector k indicating its direction of propagation, to which are associated two perpendicular vectors, the electric (E) and magnetic (B) fields, each oscillating at the frequency of the wave, and both at right angles from k . Natural light is not polarized, that is, the E vector orientation and amplitude are random. If the electric vector is always in the same plane, the light is said to be linearly polarized. If it rotates around its axis of propagation, with constant amplitude, the light is said to be circularly polarized with two possible helicities, right or left, compared to the direction of the wave vector k . Ultraviolet circularly polarized light (UV-CPL) is suspected by some to be at the origin of enantioselectivity of chiral molecules, an idea originally proposed by Louis Pasteur as early as 1848.

History

Although the proper description presented above dates back to Maxwell with his theory of electromagnetism (1864), the idea that light behaves as a wave, as opposed to a collection of particles (Newton and later Einstein) had been discussed at length by Huygens. Following the famous interference fringes and diffraction experiments from Fresnel and later Young, most if not all the physicists of the nineteenth century admitted the theory of light waves. Polarization was well known at the time of Pasteur, especially linear polarization, a relatively easy to observe phenomenon. It was noted that some substances are able to rotate the plane of polarization when they are traversed by linearly polarized light. Schematically, Pasteur discovered that some “living” substances, molecules extracted from living organisms, systematically deflect the plane of polarization to the left. Abiotic substances of the same nature do not deviate at all this plane. In physics, this is explained by the symmetry of the chiral molecule responsible for the effect, where the term chiral refers here to organic molecules containing an

asymmetric carbon, a carbon whose four valences are bonded to different molecular subgroups. Most amino acids are chiral. Abiotically synthesized amino acids are generally racemic (composed equally of left- and right-handed molecules). In living systems, they are mostly homochiral, and left-handed, a property noted by Pasteur that he attributed at the time to “unknown forces at work in the cosmos,” somehow linked to the origin of life.

Overview

Although many ideas have been proposed to explain ► [homochirality](#) with a deterministic origin (Bonner 1991), the most commonly cited is the interaction of UV-CPL with asymmetric (chiral) organic molecules (Bailey 2001). Indeed, this can be simply understood by considering the reverse effect observed by Pasteur. If polarized light can turn its polarization plane while passing through a homochiral assembly of molecules, an action called optical activity, the reverse, obtaining an enantiomeric excess while passing UV-CPL through a racemic mixture, must be true. This refers to Curie’s Principle (Curie 1894) who was the first to coin this term “chiral photons” or “racemic light.” At a molecular level, asymmetric molecules are known to possess a property called circular dichroism, which ensures that a given molecule (e.g., a left or right enantiomer) reacts differently when submitted to UV-CPL with L or with R helicities. Thus, interaction of UV-CPL with chiral molecules may help enantioselective processes to obtain nonracemic molecular materials. To be meaningful for prebiotic chemistry, a scenario has been proposed in which interstellar organic molecules are illuminated by UV-CPL radiation that exists in some places in space (Cronin and Risse 2006; Meierhenrich 2008). Selection of one enantiomer (L) over the other (D) is certainly possible in astrophysical environments, since some amino acids in meteorites display slight enantiomeric excesses (e.e.) only of the L form. Amplification to homochirality (Soai et al. 1995) is considered as a viable and common phenomenon, as even a slight enantiomeric excess

(around 1%) is able to start this amplification. Thus, UV-CPL experiments on amino acids have shown since 1974 (Balavoine et al. 1974) that asymmetric photolysis can create some excesses, and more recently this effect has been confirmed in the solid state (Meierhenrich et al. 2005). For a valid astrophysical application, these experiments have been transposed to photochemical simulations on interstellar “dirty” ices using UV-CPL from a synchrotron radiation beam to obtain non-racemic amino acids. These difficult experiments, up to now inconclusive, are still under development (Nuevo et al. 2006). Recently, these experiments on analogues of dirty interstellar ices have succeeded to produce a significant enantiomeric excess in one amino acid, alanine, the sign of which (L or D) changing with the helicity of the UV-CPL is used at the beamline DESIRS of the SOLEIL synchrotron (France). This result, described by de Marcellus et al. (2011), gives some support to the idea that interstellar molecules such as amino acids of a given enantiomeric excess (L, such as the ones found in meteorites) may have seeded the Earth, prior to the onset of homochirality. This scenario is still in the making with running experiments now dedicated to sugars.

Definition

Polycyclic aromatic hydrocarbons (PAHs) are organic molecules containing two or more fused ► [benzene](#) rings that are arranged in a honeycomb structure with hydrogen attached to the edges of the molecule. When used in the context of astrophysical research, the term “PAHs” often refers to a broader class of related molecules, including fully or partially hydrogenated or dehydrogenated PAHs, and chemically modified PAHs where one or more hydrogen or carbon atoms are replaced by another element (e.g., nitrogen) or metallocomplexes.

Overview

Polycyclic aromatic hydrocarbons (PAHs) are a large class of organic molecules containing – strictly speaking – only carbon and hydrogen. On Earth, they are found as tarry materials that are naturally present in, for example, coal and crude oil. They are formed by combustion processes of many carbonaceous substances and are thus also found in auto exhaust, candle soot, and tobacco smoke. Although some PAHs are used in medicine, public awareness of PAHs is most often raised because of their known carcinogenic properties and their long-term stability, which thus implies a persistent detrimental effect on their environment, for example, when present in soil.

In space, PAHs are observed at high abundances in our ► [Milky Way](#) galaxy wherever ultraviolet radiation is present, and they pervade the universe far beyond, as is clear from their detection in galaxies at high ► [redshifts](#). PAHs are primarily observed through their emission features at infrared wavelengths – the so-called → unidentified infrared (UIR) bands – that dominate the infrared (IR) spectra of almost all environments, including the ► [interstellar medium](#) (ISM), ► [reflection nebulae](#), star-forming regions, evolved stars, and entire galaxies. No less than

20–30% of the galactic IR radiation is emitted in these PAH bands, and it is estimated that about 10% of the cosmic carbon is locked up in these molecules. PAHs thus represent a large class of complex ► [molecules in space](#).

PAHs form in the outflows of evolved and dying carbon-rich stars and are further processed as they voyage out to the ISM and become part of protostellar environments. In addition, PAHs can also form in the ISM. Given their large abundance, their stability, and their presence in these diverse environments, it is clear that they play a crucial role in many physical and chemical processes in circumstellar and interstellar media. Furthermore, their strong IR emission features are easily observed and show subtle variations in their spectral appearance that depend on various parameters. PAHs are thus ideal tools to probe the environmental conditions in a wide range of astronomical objects.

There is an extensive body of literature about PAHs in astrophysical environments; we refer in particular to the reviews by Allamandola et al. (1989), Puget and Léger (1989), Tielens (2005, 2008, 2021), the proceedings: “PAHs in the Universe” (2011; further referred to by JTPAHs), Li (2020), and Peeters et al. (2021).

Structure

The ability of carbon atoms to have four chemical bonds allows them to form complex structures. Carbon atoms can be configured into planar hexagonal rings – benzene rings – where each carbon atom is bound to three neighboring atoms (either C or H) by covalent σ -bonds (Fig. 1). These bonds result from overlapping sp^2 -hybridized orbitals in the same plane, and thus, a planar molecular structure results. The remaining six electrons (one belonging to each carbon atom) in a benzene ring correspond to p orbitals that have lobes perpendicular to this plane. Overlap of these orbitals then results in a delocalized π -bond with molecular orbitals above and below the plane of the molecule. Such a configuration is called an aromatic bond. Hydrocarbon molecules that do not contain aromatic bonds are called aliphatic compounds.

Polycyclic Aromatic Hydrocarbon, Fig. 1 The chemical structure of benzene, some cata- and peri-condensed PAHs, and other forms of carbon and PAH-related species.

A bay region is indicated, and irregular PAHs are exemplified by 2,3;12,13;15,16-tribenzoterrylene ($C_{42}H_{22}$; adapted from Boersma 2009)

Benzene rings are then the basis for much larger molecules that are composed of several fused rings and therefore called polycyclic. If these polycyclic molecules contain only carbon and hydrogen, they are called polycyclic aromatic hydrocarbons (PAHs, chemical definition). Some chemical modifications might be common in astrophysical environments and change the molecular and spectral properties. For example, when a hydrogen atom is replaced by deuterium, the deuterated PAHs are sometimes called PADs. A PAH molecule where one or more carbon atoms are replaced by nitrogen is a polycyclic aromatic nitrogen heterocycle (PANH).

PAHs are thus a large family of different molecular species with a similar (honeycomb-like) structure. The PAH molecules themselves can be used for even larger structures. PAH platelets are stacks of PAH molecules ordered in parallel layers; PAH clusters contain several PAHs in various ordered configurations. ► [Amorphous carbon](#) is then a random combination of PAH platelets and PAH clusters.

Note that in an astrophysical context, the term “PAHs” is not only used to refer to the strict

chemical definition of PAHs but also includes PAH-like species such as, for example, PAHs in which an H is substituted by D or a functional group and PAHs in which an atom is replaced by another atom, metallocomplexes, etc. Also, there are many other molecular species made of carbon, such as carbon chains, ► [fullerenes](#), nanotubes, ► [\(nano-\) diamond](#), etc. (see Fig. 1), and many of these exist in space.

Basic Methodology

At astronomical distances, we can only study PAHs through their interaction with electromagnetic radiation. PAHs exhibit electronic transitions in the ultraviolet (UV) and at optical wavelengths, but the presence of PAHs in space is thus far primarily established through their bright emission at IR wavelengths where they have strong vibrational transitions. Some PAHs have pure rotational transitions at radio wavelengths, and indeed, two small PANHs and a pure PAH have recently been detected at radio wavelengths (see below).

Infrared Spectroscopy of PAHs

Given the emphasis on the IR characteristics of PAHs, a good understanding of the fundamentals of ► [infrared molecular spectroscopy](#) is in place here.

The energies associated with the vibrational motions between the atoms that make up a molecule are quantized and are such that the transitions between two vibrational levels occur at IR wavelengths. A molecule composed of N atoms is characterized by a unique set of $3N - 6$ allowed vibrational modes (and thus a unique IR spectrum), which allows astronomers – at least in principle – to identify specific molecules by means of IR spectroscopy. Moreover, the bandwidths and intensity ratios between different vibrational bands depend on various parameters (e.g., temperature, density); thus, the IR spectra of molecules contain information on the physical properties of the environments in which they reside. This makes IR molecular spectroscopy a very powerful tool.

However, there is a complicating factor when dealing with collections of large molecules that have a similar structure, such as PAHs. In that case, certain vibrational modes are present in each species. This is typically the case for stretching modes (where the vibrations correspond to changes in bond length between two atoms) and bending modes (where the bond angle between two atoms changes) involving only C and H atoms. The energy required to excite, for example, the C-H stretching mode is similar in all PAH molecules, and thus all PAHs will have a C-H stretching transition at nearly the same wavelength. Although each species in the set will still have its own unique vibrational spectrum, the features due to the common modes will overlap. Typically, a combined spectrum then has strong features where these common modes overlap, but the weaker features that are specific to individual molecules are washed out.

The Unidentified Infrared (UIR) Bands

In the early 1970s, new IR instruments on ground-based and airborne telescopes revealed broad emission features at 3.3, 6.2, 7.7, 8.6, and 11.2 μm in ► [planetary nebulae](#), star-forming

regions, and ► [reflection nebulae](#) (Fig. 2). Since the carriers of these features remained unknown for almost a decade, they were dubbed the unidentified infrared (UIR) bands, a name still in use today.

In the past two decades, the unprecedented views of the IR universe offered by the ► [Infrared Space Observatory](#) (ISO) and the ► [Spitzer Space Telescope](#) showcased the spectral richness of the UIR spectrum. Observations with these facilities and ground-based telescopes revealed additional weaker bands (at 3.4, 3.5, 5.25, 5.75, 6.0, 6.6, 6.9, 7.2–7.4, 8.2, 10.5, 10.8, 11.0, 12.0, 13.5, 14.2, 15.8, 16.4, 16.6, 17.0, 17.4, and 17.8 μm) perched on top of broad emission plateaus (at roughly 3.2–3.6 μm , 6–9 μm , 11–14 μm , and sometimes 15–20 μm); these weaker features are apparent in some – but not all – astronomical objects. A band at 19 μm was at one point considered to be part of the PAH spectrum; however, it shows a different spatial distribution than the PAH bands in the reflection nebula NGC 7023 (Sellgren et al. 2007) and is now generally assigned to C_{60} (Cami et al. 2010; Sellgren et al. 2010; see entry on ► [Fullerene](#)). The 17.4 emission feature is due to both PAHs and C_{60} .

The UIR bands have now been observed in almost all astrophysical environments where UV radiation is present, including the diffuse ► [interstellar medium](#), the edges of ► [molecular clouds](#), ► [reflection nebulae](#), young stellar objects, star-forming regions, C-rich Wolf-Rayet stars, C-rich post-AGB stars, C-rich ► [planetary nebulae](#), novae, nuclei of galaxies, normal galaxies, starburst galaxies, and ultra-luminous IR galaxies (ULIRGs) out to redshifts of ~ 4 . The carriers of the UIR bands are thus ubiquitously present throughout the universe, must be stable, and represent an important cosmic component in the astronomical mixtures of gas and dust.

The UIR Bands and PAHs

In the early 1980s, it was recognized that the UIR features coincide with the vibrational modes characteristic of aromatic materials (Duley and Williams 1981). Since then, many different carriers have been proposed, such as ► [hydrogenated amorphous carbon \(HAC\)](#), ► [quenched carbon](#)

Polycyclic Aromatic Hydrocarbon, Fig. 2 The ISO-SWS spectra of the planetary nebula NGC7027 and the photodissociation region (*PDR*) at the Orion bar and the Spitzer-IRS spectrum of the nuclear region of the galaxy NGC4536 illustrate the richness and variety of the PAH spectra (shown in *red*). Also indicated are the aromatic

mode identifications of the major PAH bands and the broad plateau emission on which the PAH bands are located. Other spectral features (not labeled) are atomic and H_2 emission lines. (Reproduced from Peeters in JTPAHs with permission from EDP Sciences)

composites (QCC), PAHs (e.g., Allamandola et al. 1989; Puget and Léger 1989) and coal, and more recently ► **nanodiamonds**, locally aromatic polycyclic hydrocarbons, and mixed aromatic-aliphatic organic nanoparticles (MAONs; Kwok and Zhang 2011). Indeed, the vibrational spectrum of almost any (purely) aromatic material can provide a global fit to the observed UIR

bands since – at the smallest scales – they have the same aromatic structure as PAHs.

However, the UIR bands are generally attributed to free aromatic molecules in the gas phase rather than to aromatic dust grains (such as HAC and QCC). This is primarily because emission at mid-infrared wavelength requires excitation temperatures of at least several hundred K, yet

the UIR bands have been detected in “cold” environments such as in ► [reflection nebulae](#) far away from the illuminating stars and in the diffuse ISM where dust temperatures are of the order of only tens of K. Furthermore, it is seen, for example, in reflection nebulae that the UIR band ratios show little variation with distance from the star. That indicates that the carriers of the UIR features can be excited to very high “temperatures” in such cold environments upon absorption of a single far-ultraviolet (FUV) photon (Sellgren 1984). This, in turn, requires the emitting species to be small. Indeed, classical 0.1 μm size grains are too large and do not become hot enough to emit at mid-infrared wavelengths in these environments; typically, sizes of the order of 10 Å are inferred (Sellgren 1984). A molecular origin is further supported by the anharmonic band profiles of several of the main UIR features and the high feature-to-continuum ratio. However, spectral variations have been observed in various environments (see below) that are not compatible with a single molecular species as carrier for the UIR bands. Thus, the general consensus is that the UIR bands originate from a family of aromatic molecules with sizes of <50–100 carbon atoms (e.g., Tielens 2005, 2008, 2021).

The physical processes that cause PAH molecules to produce the IR emission bands are relatively well understood qualitatively. Absorption of a far-ultraviolet (FUV) photon by a PAH molecule that is originally in the electronic and vibrational ground state induces a transition to an excited electronic state. The excited molecule then makes rapid isoenergetic transitions to a lower-lying electronic state, leaving most of the initial excitation energy in the form of vibrational energy. Subsequently, this highly vibrationally excited molecule cools down, mainly by IR emission in its vibrational modes. After it has cooled down, it will remain cold (~ 10 K) for a long time until it absorbs another FUV photon. For a typical interstellar (IS) PAH with 50 carbon atoms ($N_{\text{C}} = 50$; throughout this text, we will use N_{C} to denote the number of carbon atoms), photon absorption occurs once a year in the diffuse interstellar medium and every 10 min in typical

► [photodissociation regions \(PDRs\)](#) such as the Orion bar (Tielens 2005).

The main UIR bands at 3.3, 6.2, 7.7, 8.6, and 11.2 μm are then attributed to various stretching and bending vibrations involving the C-H and C-C bonds in PAH molecules with $N_{\text{C}} \approx 50$ –100. In particular, the 3.3 μm band is due to C-H stretching modes, and the 6.2 μm band to C-C stretching modes. C-H in-plane bending modes are responsible for the 8.6 μm band and coupled C-C stretching and C-H in-plane bending modes for the 7.7 μm complexes. The 11.2 μm band is caused by C-H out-of-plane bending modes. Vibrational transitions at wavelengths longward of 15 μm involve motions of the entire molecular skeleton and hence are more specific to each molecule.

Laboratory measurements and theoretical calculations indicate that the PAH molecules have low-frequency vibrational modes at far-IR wavelengths (Boersma, Joblin in JTPAHs). These low-frequency vibrational modes of PAHs are skeleton or drumhead modes sensitive to the entire structure of the molecule. Detecting these modes would further constrain the PAH population and could possibly lead to the identification of a single molecule. As these far-IR modes are intrinsically very weak (about 1% of the strong mid-IR modes, Mulas et al. 2006) and do not overlap with different molecules, they have not been detected yet.

It is important to realize that the carriers of the UIR bands may not all be “pure” PAHs (following the strict chemical definition). Stable PAH-like structures can be made, for example, by substituting one or more C atoms for N, O, or Si. Similarly, H atoms could be replaced by deuterium, by aliphatic carbon chains, or by molecular side groups. However, such substitutions leave a clear spectral imprint (see below), and spectroscopic analyses of the UIR bands in the interstellar medium show that at most 2% of the aromatic H can be substituted by methyl groups ($-\text{CH}_3$) and at most 6% by superhydrogenated PAHs (i.e., PAHs with an extra H attached to a peripheral C), both based on the strongest aliphatic emission feature observed in the interstellar medium (at 3.4 μm ; Tielens 2021).

Although the assignment of the UIR bands to vibrational modes from a collection of PAH molecules is now generally accepted, specifics of the emitting population remain elusive. This is due to the fact that the clear spectral signatures of the vibrational modes of PAHs are primarily governed by the physical conditions of the environment (which is the same for all PAHs) and show only a weak dependence on size and structure.

Electronic Transitions of PAHs

The electronic transitions of PAHs occur at UV and optical wavelengths, where the precise transition properties depend primarily on size (and somewhat on charge). Given their large abundance in the interstellar medium inferred from their infrared emission, PAHs are thus often suggested to play a role in various observational phenomena related to interstellar extinction. In particular, PAHs are at least a contributing species to the 217.5 nm extinction hump (see ► [UV Absorption Bump](#)) and are also considered as possible carriers of the ► [diffuse interstellar bands \(DIBs\)](#). They might furthermore also be responsible for the ► [extended red emission \(ERE\)](#) and the blue luminescence.

The 217.5 nm band is by far the strongest feature in the interstellar extinction curve and exhibits a fairly constant wavelength but a variable width in different lines of sight. Many individual species have been proposed as carriers of this feature, but the consensus is that this extinction hump is due to a plasmon resonance in carbonaceous material. PAHs must thus contribute to this feature. Laboratory experiments have shown that mixtures of PAHs with sizes larger than 22 carbon atoms result in a 217.5 nm hump that is as smooth as the observed interstellar hump, while mixtures of smaller PAHs exhibit many narrow features. The exact wavelength of the hump depends on the average size of the PAHs, and calculations show that an average interstellar PAH size of 50–60 carbon atoms is required to reproduce the observed peak wavelength of the 217.5 nm hump.

The DIBs are a set of hundreds of absorption lines observed from the near-UV to the near-IR

in the spectra of reddened stars (Herbig 1995; Sarre 2006). Their interstellar origin is now well established, but their carriers remain unidentified, with the exception of two strong and three weaker DIBs in the near-IR that have been recently identified as due to C_{60}^+ (Campbell et al. 2015; Linnartz et al. 2020). Many observational studies point to abundant gas-phase molecules that are able to survive the interstellar radiation field. PAHs (and especially PAH cations) are thus very promising candidates, although the same arguments could favor carbon chains and fullerene compounds. Some consensus is now growing that “normal,” pure PAHs cannot be the carriers of the strong DIBs (Cami and Cox 2014). Note that this does not exclude PAH radicals and PAH-metal complexes as DIB carriers.

Rotational Spectroscopy

Neutral PAHs generally have no permanent dipole moment, and thus, they exhibit no allowed rotational transitions. Exceptions are open-shell species (e.g., the polycyclic aromatic nitrogen heterocycles or PANHs) and nonplanar molecules (e.g., the bowl-shaped corannulene, $C_{20}H_{10}$). Also, PAH cations exhibit rotational transitions. Rotational properties have been reported for a few molecules (Tielens 2008 and reference therein) facilitating dedicated searches for these species. Recently, ► [benzonitrile](#) ($c\text{-C}_6\text{H}_5\text{CN}$; McGuire et al. 2018), 1- and 2-cyanonaphthalene (a derivative of the two-ring PAH naphthalene ($C_{10}H_8$) in which a H-atom is substituted by a nitrile ($C \equiv N$) functional group; McGuire et al. 2021), and indene ($c\text{-C}_9\text{H}_8$, Cernicharo et al. 2021, Burkhardt et al. 2021) have been detected in emission towards the molecular cloud TMC-1 constituting the first identification of individual PAH molecules in space.

PAHs might also contribute to the galactic anomalous foreground emission. This excess microwave emission at frequencies from 10 to 100 GHz has an interstellar origin and is strongly correlated with the dust IR emission. Its origin is still somewhat debated but is generally attributed to emission from spinning ► [interstellar dust grains](#) (Draine and Lazarian 1998). The

anomalous emission can be well reproduced by theoretical models of spinning PAHs that adopt PAH properties that are in good agreement with those derived from their mid-IR emission (Ysard et al. 2010).

PAHs in the Solar System

For completeness, we note that PAHs have also been observed and found in situ in various objects in the Solar System (e.g., ► [meteorites](#), interplanetary dust particles, ► [comets](#), ► [Titan](#)).

Key Research Findings

Characteristics of the Astronomical PAH Family

We have learned most of what we know about PAHs in space from detailed analyses of their IR emission features – the UIR bands. The UIR bands observed in a large variety of environments are remarkably similar, and in first order, a generic UIR spectrum emerges. Detailed observational studies, however, have revealed a multitude of spectral variations in peak positions, shapes, and (relative) intensities from source to source, and also spatially within extended sources. The interpretation of the UIR bands and these spectral variations is strongly based upon theoretical and experimental spectroscopy of PAHs and related species. Laboratory experiments and theoretical models reveal how PAH spectra change as a function of parameters such as temperature, charge, size, and the precise molecular (edge) structure. This information can then be used to determine the cause of the observed spectral characteristics in astronomical observations. This comparison uncovers some properties of the astronomical PAH family, as well as their relation to specific environmental parameters.

Distribution and Abundance

As is unequivocally evident from the observations, PAHs pervade the universe: they are found in almost all sources with associated gas and dust within our ► [Milky Way](#) and in many galaxies near and far (up to a redshift of ~ 4). Exceptions are regions with extreme radiation fields or fast

shocks, since PAH molecules cannot survive in these environments, and regions well shielded from UV radiation, as in the dense interiors of molecular clouds where PAHs get frozen into the ice mantles on the grain surfaces. Furthermore, the UIR bands generally dominate the IR spectra of these sources. The total emitted power in all the UIR bands combined ranges from a few percent to about 10% of the total power budget of galaxies. Hence, PAHs are very abundant in space: for a typical PAH size of 50 carbon atoms, the total PAH abundance by number is $\sim 3 \times 10^{-7}$ relative to the number of hydrogen atoms (Tielens 2005).

Charge State

One of the early pivotal results of the laboratory and theoretical studies on PAHs is the remarkable effect of ionization on the infrared spectra. While peak positions are only modestly affected, the influence on intensity is striking: the C-C bands in the 5–10 μm regions grow from the smallest features to become the dominant bands upon ionization. Although anions and multiply charged large PAHs are less studied, they exhibit a similar increase of emission in the C-C modes in the 5–10 μm regions relative to the C-H modes at 3.3 and 11.2 μm .

The corresponding C-C and C-H modes of the UIR bands do show strong variations in their relative strengths from source to source, and even within extended sources, suggestive of changes in the charge state of the astronomical PAHs (Fig. 3). The CH out-of-plane bending modes, however (in the 10–15 μm regions), do not behave consistently: the 12.7 μm PAH band correlates well with the 6–9 μm modes and not with the 11.2 μm PAH.

Note that several other parameters may influence the observed C-C/C-H intensity ratio; however, several studies indicate that changes in the degree of ionization of the PAHs are the main factor in these different environments (e.g., Hony et al. 2001; Galliano et al. 2008).

Chemical Composition

The PAH band profiles show pronounced variability, in particular for the C-C modes (6.2 and 7.7 μm bands). These variations define four

Polycyclic Aromatic Hydrocarbon, Fig. 3 (Left) The correlation of the 3.3 and 11.2 μm band strengths normalized to the 6.2 μm band strength. Circles are HII regions, stars intermediate mass star-forming regions, squares are reflection nebulae, and triangles are planetary nebulae (Hony et al. 2001; reproduced with permission © ESO). (Right) The variation in the C-C/C-H band ratios (see

Fig. 2) within the starburst galaxy M82. The gray-filled area represents the correlation obtained for the integrated spectra of a large sample of galactic and extragalactic sources. The red symbol is the value of the global measurement over the entire galaxy. (Galliano et al. 2008, reproduced by permission of the AAS)

classes, A, B, C, and D (Fig. 4; Peeters et al. 2002; van Dienenhoven et al. 2004; Matsuura et al. 2014), each having different band profile characteristics. Class A and B sources show the “classical” UIR features at 6.2, 7.7, and 8.6 μm , but class B profiles are slightly redshifted compared to class A. Moreover, the 7.7 μm complex has a dominant 7.6 μm component in class A sources while class B sources show a dominant component in this complex peaking between 7.8 and 8 μm . Class C and D band profiles are significantly different from classes A and B: they show a very broadband peaking at $\sim 8.2 \mu\text{m}$ and $\sim 7.8 \mu\text{m}$. Class A and C sources show little variation in their profiles at these wavelengths, moderate variations are present within class D while large differences are present within class B. The observed variations in the UIR spectra seem to span a continuous distribution going from class A via class B to class D and C.

Although several properties could in principle determine the precise peak positions of the C-C stretching bands, a strong constraint is offered by the fact that the position of the 6.2 UIR band in

class A sources cannot be reproduced by the C-C stretching mode of pure PAHs (Peeters et al. 2002; Hudgins et al. 2005) using the currently available laboratory and theoretical data. The observed variations in the band profiles thus seem to reflect a (chemical) modification of the PAHs. Various PAH-related species have been proposed:

- PANHs: substitution of a C atom by an N atom in a PAH systematically shifts the position of the strongest C-C stretching mode toward shorter wavelengths while having no systematic effects or shifts on the position of other vibrational modes.
- Aromatic-aliphatic carbonaceous species with different degree of aromaticity (see below).
- PAH clusters: for example, PAH dimers and trimers.
- PAH-metal complexes: these are species in which a metal atom is located either below or above the carbon skeleton.

Additionally, structural modifications to PAHs may also involve the H atoms and include:

Polycyclic Aromatic Hydrocarbon, Fig. 4 An overview of the source-to-source variations in the position and profile of the main UIR bands in four wavelength bands. Large variations are evident in the 6–9 μm regions. Class A peaks at the shortest wavelengths and class B at

longer wavelengths. The C-C modes of class C peak at even longer wavelengths. (Peeters et al. 2002; van Dienenhoven et al. 2004, reproduced by permission of the AAS)

- Superhydrogenated and protonated PAHs: These PAHs contain peripheral C atoms bonded to two hydrogen atoms. Hence, these species have aliphatic CH bonds which emit near 3.4 μm (Fig. 2). This band is observed in many sources but is generally weak. Also, emission at this wavelength may be due to methyl side groups attached to PAHs.
- Deuterated PAHs: Peeters et al. (2004c) and Doney et al. (2016) detected weak emission bands at 4.4 and 4.6–4.8 μm , characteristics

of the C-D stretching mode in PADs and D_n -PAHs in 7 star-forming regions. While the aromatic C-D stretch is very weak, the derived D/H ratio for the aliphatic bands is very large compared to simple molecular species, suggesting that deuterium fractionation is very specific. However, many star-forming regions do not exhibit emission in these modes, implying that conditions necessary for deuteration are not common in the ISM. Nevertheless, the presence of deuterated PAHs can

still contribute to the observed variations in the gas-phase D/H ratios for different lines of sight.

- Side groups: Hydrogen can be replaced by chemical side groups. The most important one is methyl group ($-\text{CH}_3$), which causes a spectral signature of $3.4\text{ }\mu\text{m}$ (Fig. 2).
- Molecular edge structure (see below).

Size

When a PAH molecule absorbs a UV photon, the absorbed energy is distributed over the vibrational modes. Since larger PAHs have many more available modes, the average energy per mode is lower. As a consequence, smaller PAHs will reach much higher levels of vibrational excitation and thus will be more conducive to emitting at shorter (more energetic) wavelengths.

Thus, the size distribution of molecules that contribute to an observed UIR band will depend on the wavelength of the band. For example, the majority of the $3\text{ }\mu\text{m}$ UIR emission is due to PAHs made up of 30 to 70 carbon atoms, while emission in the $10\text{--}15\text{ }\mu\text{m}$ region originates from much larger PAHs, with sizes between 80 and several hundred carbon atoms (Schutte et al. 1993). Clearly, the astronomical PAH family must represent a size distribution. The best probe for PAH size is the $3.3/11.2$ intensity ratio as these bands cover the largest wavelength range, which is thus most sensitive to PAH size (and thus excitation), and both bands arise from CH modes in neutral PAHs. Observed PAH sizes are between 50 and 110 C-atoms in a handful of ISM sources (Croiset et al. 2016; Knight et al. 2021).

Laboratory and theoretical studies of PAHs also show clear spectral differences between small and larger PAHs. The spectra of small PAHs are rather diverse, while larger PAHs emit more consistently at the same wavelengths. However, very large PAHs ($N_{\text{C}} > 150$) exhibit complex spectra unlike those observed in space. In addition, small changes in peak position occur with changing PAH size and contribute to the band profile variations (primarily in class A and B).

At the same time, though, the astronomical PAH family is most likely somewhat limited,

since the astronomical observations are very similar to first order and do not show the numerous variations that could be expected for millions of PAHs with all possible sorts of structures. This is also clear from the emission in the $15\text{--}20\text{ }\mu\text{m}$ regions, which is due to carbon skeleton modes and hence more molecule-specific. However, the astronomical spectra only exhibit a limited number of bands and/or a broad emission feature. This led to the grand PAH hypothesis, that is, the idea that only a few large compact PAHs dominate the PAH family (Andrews et al. 2015).

Molecular (Edge) Structure

Laboratory studies show that the peak wavelength of the C-H out-of-plane bending mode depends strongly on how much the bond is influenced by the presence of neighboring hydrogen atoms and, more specifically to the number of adjacent peripheral C-atoms bonded to an H-atom (Bellamy 1958). While the details depend slightly on the charge state of the carrier, it is clear that the 11.0 and $11.2\text{ }\mu\text{m}$ features are due to solo C-H groups (i.e., there is no adjacent C atom that is bonded to an H atom), while both duos and trios (respectively two and three adjacent C-atoms each with an H attached to them) contribute to the $12.7\text{ }\mu\text{m}$ feature. Variations in the relative strength of these out-of-plane bending modes are thus indicative of variations in the molecular edge structure of the emitting PAHs. Indeed, the solo CH groups decorate long, straight, and smooth edges, while duos and trios are characteristic of corners and irregular edge structures.

Circumstellar PAHs associated with planetary nebulae have a very strong $11.2\text{ }\mu\text{m}$ band, and a much weaker $12.7\text{ }\mu\text{m}$ band (Fig. 2) and are therefore characterized by very compact molecular structures. On the other hand, the $11.2\text{ }\mu\text{m}$ band in interstellar PAHs is about as strong as the $12.7\text{ }\mu\text{m}$ band (Fig. 2), indicating that interstellar PAHs have more corners, either because they are (on average) smaller or they are more irregular larger species (Fig. 1, Hony et al. 2001; Bauschlicher et al. 2008, 2009).

Laboratory and theoretical studies also reveal that H atoms located in a bay of the edge structure (see Fig. 1) have emission at slightly shorter

wavelengths compared to that of non-bay H's. This difference can be used to estimate the smoothness of the edge structure (Bauschlicher et al. 2009). In addition, a varying degree of bay Hs has been put forward to explain variations in the 3.3 μm band profile (Candian et al. 2012). The degree of bay Hs also influences the 7–9 μm emission (e.g., Peeters et al. 2017).

Astronomical Observations Versus PAH Databases

One of the strongest criticisms against the PAH hypothesis (i.e., the identification of the UIR bands with emission from PAHs and PAH-like species) has been the lack of a good match between a combination of experimental and/or theoretical PAH spectra, and the astronomical UIR spectra. This has been largely due to the limited availability of spectral properties for a large number of PAH species. Several databases now exist containing over 4000 spectra (Bauschlicher et al. 2010, 2014, 2018, Mattioda et al. 2020, <http://www.astrochem.org/pahdb/>; Mallocci et al. 2007), and good fits for astronomical observations of all three classes have been obtained (Fig. 5, Cami in JTPAHs [2011]). Spectral decomposition of the fits can be used to reveal the contribution of PAHs of different sizes, charge states, and differing compositions (e.g., Boersma

et al. 2013). Such work confirms and extends many of the conclusions discussed above.

The PAH Life Cycle

Carbon stardust is formed in the outflow of C-rich AGB stars and is believed to be comparable to terrestrial soot formation in flames – where PAHs are formed. Carbon star outflows are thus believed to be the birthplace of astronomical PAHs. Most of the carbon in these outflows is tied up in CO and C_2H_2 ($\blacktriangleright$ [acetylene](#)); chemical models then predict the formation of $\blacktriangleright$ [benzene](#), PAHs, and ultimately soot (Tielens 2008 and reference therein). There is little direct evidence of PAHs in the outflows of C-rich AGB stars though, possibly because of the absence of UV radiation from these stars. Indirect evidence, however, is provided by the ample detection of PAHs in the subsequent evolutionary stages characterized by much stronger UV radiation: the C-rich post-AGB stars, and C-rich $\blacktriangleright$ [planetary nebulae](#). Eventually, the material in these outflows becomes part of the $\blacktriangleright$ [interstellar medium](#) and conglomerates into $\blacktriangleright$ [diffuse clouds](#) that grow in size and evolve into $\blacktriangleright$ [molecular clouds](#). In the dense cores of molecular clouds, PAHs get frozen into the ice mantles covering grain surfaces. The cores of molecular clouds will eventually become proto-stars, at which point the PAH molecules are

Polycyclic Aromatic Hydrocarbon, Fig. 5 The astronomical UIR spectra (black) and the best fit PAH model spectra (red) for three types of PAH sources. Residuals are shown in green. This PAH model is able to fit all three classes. The HII region IRAS 23133 + 6050 (black) is a class A source; the Red Rectangle (red) a class B source; and the protoplanetary nebula IRAS 13416-6243 (blue) a class C object. (Cami in JTPAHs, reproduced with permission from EDP Sciences)

released into the gas phase and may be incorporated into a planetary system.

PAHs may undergo dramatic changes due to UV and collisional processing, coagulation, accretion, shattering, etc., that are associated with different phases of this life cycle. In addition, shattering of grains by shocks or UV processing of PAH clusters may form PAHs in the interstellar medium (top-down approach). Furthermore, the recent detections of small PAHs in the molecular cloud TMC-1 also suggest PAH formation in the ISM through a bottom-up approach.

There is ample observational evidence for these processes:

- Analysis of the spatial behavior of PAHs within extended sources reveals the photochemical evolution of the PAH family. We list a few examples here. PAHs are prominent toward the edge of PDRs but further inward the PDR (characterized by less UV radiation), larger species (such as PAH clusters) are found. These studies suggest that the destruction of PAH clusters by UV photons results in the formation of PAHs. These PAH clusters themselves may be reformed in the denser and more shielded environments of molecular clouds (e.g., Berné, Rapacioli in JTPAHs, Pilleri et al. 2012). In addition, the derived size of the PAH molecules increases with increasing FUV radiation field strength, indicating that small PAHs are destroyed in regions of high UV radiation (Croiset et al. 2016; Knight et al. 2021). Moreover, the PAH abundance decreases while the C_{60} abundance increases with increasing UV radiation field strength in NGC7023 suggesting that PAHs are converted to C_{60} under UV processing (Berné and Tielens 2015). In addition to PAH size, UV radiation also influences the charge balance and the molecular (edge) structure (e.g., Boersma et al. 2013; Peeters et al. 2017), revealing, amongst others, that different PAH subpopulations contribute to individual PAH emission bands.
- The specific profiles of the UIR bands depend directly on the type of object (Peeters et al. 2002; van Dienenhoven et al. 2004): class

A profiles represent ► **HII regions**, non-isolated Herbig AeBe stars, ► **reflection nebulae**, interstellar medium, and entire galaxies; class B contains most ► **planetary nebulae**, isolated Herbig AeBe stars, and a few post-AGB stars; and class C and D are mainly comprised of post-AGB stars. Thus, class A profiles are associated with interstellar material, while classes B, C, and D profiles correspond to circumstellar material; the differences between the classes are due to PAH processing. These spectral variations are also seen within spatially extended objects such as reflection nebulae and evolved stars (e.g., Peeters in JTPAHs, Candian et al. 2012, Rosenberg et al. 2011, and Boersma et al. 2013).

- In a sample of post-AGB stars and isolated HAeBe stars (all of PAH class B or C), Sloan et al. (2007) found a remarkable anticorrelation of the peak positions of several of the UIRs with the effective temperature of the exciting star (Fig. 6), suggesting that the components of the PAH family are susceptible to UV processing. This has been interpreted as a varying importance of aliphatics versus aromatics (e.g., Sloan et al. 2007; Boersma et al. 2008, Acke in JTPAHs, Kwok and Zhang 2011) instead of a change in size distribution of the PAH family. Aliphatic carbonaceous species are known to produce broader emission bands compared to PAHs and hence are put forward as the carrier of the class C 7.7 μm complex. An evolution to class B and then to class A is then the result of more UV processing (e.g., due to an increase in effective temperature) of these aliphatic carbonaceous species, destroying the aliphatic bonds and hence increasing the aromaticity of species. However, the observational relation does not hold in general. Indeed, several planetary nebulae and class A objects do not follow the correlation; moreover, the PAH bands of Herbig AeBe stars with the same effective temperature can belong to both classes A and B (Boersma et al. 2008). These exceptions seem to suggest that in addition to or in contrast with a dependence on effective temperature, other parameters may play a role such as, for example, the history of the material (prolonged

Polycyclic Aromatic Hydrocarbon, Fig. 6

The central wavelengths of the 7.7–8.2 and 11.3 μm UIR features versus the effective temperature of the host star. (Sloan et al. 2007; Keller et al. 2008, reproduced by permission of the AAS)

exposure to a strong radiation field in the photosphere of a disk; Tielens 2021).

- For galaxies harboring an active galactic nucleus (AGN, thought to indicate the presence of a supermassive black hole), the PAH emission differs considerably. The 6 to 9 μm emission is often suppressed relative to the 11.2 μm emission (Li 2020 and references therein). While still under investigation, this suppression has often been attributed to the preferential destruction of small PAHs by the hard radiation field of the AGN.
- For galaxies, the relative importance of PAHs with respect to dust grains in the spectra depends on the hardness of the radiation field and the ► [metallicity](#) (Li 2020 and references therein). These two parameters are related, and it is thus difficult to distinguish between an origin in a less efficient PAH formation process (since less carbon is available at lower metallicities) and increased PAH processing (modification and/or destruction of PAHs by the hard radiation field).

The Role of PAHs in Astronomical Environments

PAH Chemistry

Several chemical processes involve PAHs in the ISM. UV processing (► [photochemistry](#)) and collisional processing can significantly alter the PAH distribution (in terms of charge and size). PAHs can furthermore chemically react with abundant atoms such as H, C, N, and O. In ► [dense clouds](#), PAHs condense out onto ice mantles, and can subsequently undergo UV processing. The photo-products are later released into the gas phase by thermal heating in the star-forming environment, or in the PDRs and by shocks or cosmic-ray ► [sputtering](#). For a detailed account of PAH chemistry, see Tielens (2005, 2021), ► [Cosmochemistry](#), ► [Interstellar chemical processes](#), and ► [Interstellar Ices](#).

Photochemistry involves photoionization and photodissociation. The ionization potential of PAHs is around 6–7 eV (electron volts) and depends on the PAH size and geometry. PAHs

can be multiple ionized, but for a typical 50 C-atom PAH, the fourth positive ionization potential is larger than 13.6 eV, which limits the ionization stage in neutral hydrogen regions. Alternatively, absorption of a UV photon may lead to the loss of a H atom (dehydrogenation) or a side group. The rates for such reactions are highly dependent on the PAH size and the side group in question: for example, hydrogen loss from a methyl group is faster than aromatic hydrogen loss, which in turn is much faster than carbon loss (i.e., C_2H_2 ejection). The size below which PAHs may lose all H (because the re-hydrogenation rate is lower than the dehydrogenation rate) is estimated to be ~ 35 C-atoms. Following complete dehydrogenation, PAHs may isomerize into carbon chains, rings, or fullerenes (Zhen et al. 2014). This process removes small PAHs from the PAH family.

Collisional processing is as important as UV processing, especially for collisions with high-velocity electrons and ions originating in shocks, hot gas, and cosmic rays (Micelotta 2009). Interstellar PAHs (~ 50 C-atoms) are destroyed in shocks with velocities greater than 100 km/s. For lower velocity shocks, PAHs survive, but their structures, and thus characteristics are severely altered by the loss of carbon atoms (20–40%). In a hot gas ($T \sim 10^3$ – 10^8 K), PAHs are destroyed through consecutive C_2 loss on the periphery of the structure primarily by He collisions in low-temperature gas ($T < 3 \times 10^4$ K) and by electronic collisions in high-temperature gas ($T > 3 \times 10^4$ K). Finally, PAHs are destroyed by cosmic rays on various timescales (depending, e.g., on the collisional particle). Depending on the environment considered (and its physical conditions), different collisional processes dominate.

Gas-phase chemistry involves the following reaction types: electron recombination ($PAH^+ + e \rightarrow PAH$), electron attachment to PAHs ($PAH + e \rightarrow PAH^-$), charge-exchange reactions involving neutral PAHs ($PAH + M^+ \rightarrow PAH^+ + M$ with M a metal), mutual neutralization reaction of PAH anions with atomic or molecular cations ($PAH^- + M^+ \rightarrow PAH + M$), and reactions involving PAH cations and H, N, and O atoms.

Laboratory studies of UV processing of PAHs trapped in ice show that the processing is confined to the peripheral aromatic hydrogen and leaves the carbon skeleton intact. The aromatic hydrogen may be substituted by side groups (e.g., OH, CH_3 , COOH, CO, and CN) to form more complex organic compounds such as, for example, quinones (Bernstein et al. 1999). Some of these photoproducts are thus prebiotic molecules and may have relevance for the organic content in space. However, the importance of PAH processing in ices in actual molecular clouds is not yet established.

Shattering of solid carbon in shocks modifies the interstellar grain size distribution (Jones et al. 1996). Typical interstellar shocks may transform 10% of the solid carbon into small carbon clusters and hence provide a pathway for PAH formation in the ISM. However, faster shocks will destroy the PAHs. Currently, little observational evidence exists for PAH formation in shocks, although Rho (in JTPAHs [2011]) discerned 15–20 μm PAH emission in supernova remnant SNR N132D in the Magellanic Clouds, while Engelbracht et al. (2006) detected PAH emission associated with the superwind of the galaxy M82 and entrained by hot shocked gas.

PAH Physics

PAHs play an important role in the physics of the ISM, primarily through their influence on the charge balance and in the heating of the ISM.

The ionization balance of PAHs is set by the ratio of the ionization rate to the recombination rate, which is equal to $G_0 T^{1/2}/n_e$ in which G_0 is the far-ultraviolet (FUV; $6 \text{ eV} < \text{photon energy} < 13.6 \text{ eV}$) radiation field in units of the Habing field (see ► [Photodissociation Region](#)), T the gas temperature, and n_e the electron density (for details, see Tielens 2005, 2021). In typical interstellar conditions, several charge stages are present simultaneously, as is also indicated by the spectra attributed to PAHs. These include neutral PAHs and ionic PAHs (either cations or anions). PAH anions provide an alternative and effective recombination path for atomic and molecular cations compared to gas-phase recombination in ► [photodissociation regions](#) and ► [molecular](#)

clouds. PAHs thus influence the charge balance and – through their influence on the equilibrium state of chemical reactions – gas-phase abundances (Tielens 2005, 2021).

In addition, PAHs and very small grains dominate the photoelectric heating of the ISM (Tielens 2005, 2021). This photoelectric heating couples the gas energy budget with the radiation field of stars in PDRs and hence determines the physical conditions in PDRs.

Applications

The intensity ratios of the CC/CH modes of the UIR bands are determined by the charge balance of the PAHs. If variations in the physical conditions are known (e.g., derived from PDR models), the observed variations of the PAH bands can be used to establish an “empirical” calibration that relates the PAH bands to the local physical conditions. Once such a calibration is known, the physical conditions can be determined based upon the omnipresent PAH bands. This can serve as a diagnostic tool for regions where, for example, the main PDR coolants are not easily observable, such as galaxies at large distances. Such an approach has been tested on a sample of three well-studied objects and has been proven to be very promising (Fig. 7, Galliano et al. 2008). Similarly, physical conditions can be derived from combining the observed PAH ionization ratio and H₂ line ratios in dense, highly irradiated PDRs (Berné et al. 2009).

UIR emission bands are particularly bright in massive star-forming regions since they are excited by strong UV radiation. Combined with their ubiquitous appearance, this makes PAH a powerful tracer of star formation throughout the universe. PAHs are indeed widely used to derive star formation rates of galaxies (Calzetti 2020), one of the key indicators for understanding galaxy formation and evolution. In combination with emission lines, they serve as diagnostics for the physical processes powering galactic nuclei.

Finally, the presence of PAHs is used to distinguish between shocked gas and PDRs (van den

Polycyclic Aromatic Hydrocarbon, Fig. 7 Empirical calibration of the 6.2/11.2 UIR band ratio as a function of the ionization parameter, $G_0 T^{1/2}/n_e$ (Galliano et al. 2008, reproduced by permission of the AAS)

Ancker et al. 2000) and to determine redshifts in distant galaxies (e.g., Yan et al. 2007).

Future Directions

Several key questions regarding astronomical PAHs remain and require further investigations. In particular:

1. How exactly do PAH characteristics (e.g., size, charge state, chemical structure) interact with and reflect the physical conditions of their environment (e.g., density, radiation field, temperature, ► [metallicity](#))?
2. How can we use the UIR bands as a probe of the physical conditions in regions near and far?
3. Can we observe long-wavelength counterparts to the well-known mid-IR PAH bands? What are their characteristics?
4. What are the spectroscopic signatures of large PAH molecules, PAH clusters, and PAH complexes?
5. Which specific molecules make up the astronomical PAH family?

6. What can we learn from the electronic transitions of PAHs, and what is their relation to the
 ► [diffuse interstellar bands \(DIBs\)](#)?

Today, the wealth of IR PAH emission bands and the large variability of the IR PAH spectra prompt more questions than can be answered with the current experimental and theoretical data. Similarly, at optical wavelengths, there are now more observed unidentified DIBs than ever before. With the upcoming launch of the James Webb Space Telescope (JWST), we live in a golden era to address these questions from the observational perspective. Indeed, with its unprecedented combination of high spatial resolution, medium spectral resolution, and high sensitivity over the IR wavelength range of relevance for PAH research, JWST will spatially resolve the chemical frontiers where the photochemical evolution of PAHs occurs. However, if we intend to make significant progress in our understanding of the PAHs, the observational effort needs to be balanced with dedicated laboratory and theoretical studies. Indeed, we can only fully exploit the treasure trove of information that is hidden in the PAH spectra by a joint effort of the observational, experimental, and theoretical tools.

Definition

Polymers of prebiotic significance are those to be found on the verge of the evolutionary onset of various catalytic cycles of chemical reaction. One typical example is the ► [formose reaction](#) of polymerizing formaldehyde into glycolaldehyde. When one glycolaldehyde molecule enters the cycle in the presence of formaldehyde, two glycolaldehyde molecules come out of the cycle at the end. Significant to the operation of the reaction cycle is that the synthesis of glycolaldehyde is not due to the direct dimerization of formaldehyde. The initiation of the cycle presumes the prior presence of trace amounts of glycolaldehyde. This convoluted nature of the cycle requiring the prior presence of the intended products symbolizes a difficulty facing the emergence of polymers of prebiotic significance.

Overview

One specific case demonstrating a simple cyclic, though not yet autocatalytic, polymerization of small organic molecules is found in the acceleration of polymerizing hydrogen cyanide in the presence of formaldehyde (Schwartz and Goverde [1982](#)). Under some fixed experimental conditions,

the initial rate of polymerization of HCN monomers up to an HCN tetramer is increased almost 100-fold within a very short period of time. Although the present cyclic polymerization up to HCN tetramer could be impressive especially in the respect of prebiotic synthesis of adenine, the reaction is also accompanied by a complex mixture of other products which might induce some deleterious effect on the focused reaction. The situation is almost similar to the formose reaction not yet sufficiently tailored enough to synthesize an adequate amount of ribose as the main ingredient of the backbone of RNA molecules. The difficulty comes from the interferences with other complex products available at the same time.

Destructive interferences between autocatalytic reactions in focus and the necessarily accompanied side-chain reactions can be conceivable even on a theoretical ground alone. A case in point is the peptide cycle (Kauffman 1986). It is one thing to expect an emergence of a set of autocatalytic peptides in a random mixture of amino acid molecules, while it is quite another to preserve the once appeared autocatalytic set for some indefinite period of time. If the random mixture is in thermal equilibrium, every forward reaction is counterbalanced by the reversed reaction as revealed in the principle of detailed balance. The appearance of a likely autocatalytic set, if any, is necessarily counterbalanced by its disappearance, with no net autocatalysis in the effect.

A rescue for saving the likelihood for the appearance of an autocatalytic set on an experimental ground may be sought in preparing specific initial conditions which are not in thermal equilibrium in themselves. If one can initially prepare appropriate peptides of 32-residue length that are carefully designed to self-associate to form stable coiled coils, they will facilitate the ligation of the accompanied N-terminal and C-terminal subsequences (Lee et al. 1996). The present ligation makes self-replication of peptides possible. An essence of the experimental operation of an autocatalytic peptide set is within the choice of uniquely designed initial conditions. This demonstration now invites us to face the issue of how the choice of the initial conditions can be naturalized.

One likely strategy for implementing the initial conditions is to update the experimental conditions frequently. A specific example for the present objective is the feeding experiment on the prebiotic synthesis of oligonucleotides and oligopeptides on mineral surfaces (Ferris et al. 1996). When the monomers activated by imidazole were fed successively onto the mineral surfaces (montmorillonite for nucleotides and elite or hydroxylapatite for amino acids), the formation of oligomers even up to 55 monomers long was confirmed.

Then the experimental endeavor for approaching polymers of prebiotic significance in a natural manner as much as possible will be found within how the experimental conditions could enhance their specificity as repeating their update without asking an intelligent help from the experimentalist every time in the process. Practicing this strategy exclusively on the theoretical ground is hardly conceivable because of the historical and evolutionary nature of the empirical or experimental counterpart. Even if molecular Darwinian process remains legitimate in its own light at least theoretically, one cannot rely upon the Darwinian process to figure out how self-replicating molecules could have got started. Some preliminary evolutionary process must have been in place so as to make the emergence of molecular Darwinian process tangible; otherwise the issue of the onset of self-replicating molecules would have to remain intangible.

One obvious clue for addressing how self-replicating molecules got started is sought within a reexamination of chemical reactions conceived in thermodynamics. Chemical reactions in thermal equilibrium certainly satisfy the principle of detailed balance, as implying that every forward reaction is counterbalanced by the reversed reaction as maintaining both the reactants and the products in equilibrium. No evolution could be in sight within the stipulation of detailed balance. However, once the condition of thermal equilibrium is lifted, the chemical reactions there may be set free from the theoretical stipulation of detailed balance.

Just for the sake of argument, let us imagine a reaction solution of monomers participating in their ligation and the resulting hydrolysis. If the reaction solution is in thermal equilibrium, the

population distributions of the monomers and the possible oligomers, especially their ratios, depend only upon the equilibrium constants or equivalently upon both the Gibbs free energies and temperatures, and not upon each rate constant. The situation would however be drastically changed if thermal equilibrium is not attainable. If the reaction solution happens to experience rapid decrease of its temperature as in the sudden transference from near hydrothermal vents in the ocean to the surrounding cold seawater, the likely products to remain must be the one that can survive the rapid quenching. The decisive factor for determining the likely product to survive is not the equilibrium constant, but is the rate constant measuring the extent of following the sudden temperature drops in the immediate neighborhood. Even if the material constituents remain the same, the most likely product to survive is the one whose internal configuration maximizes the rate constant for following rapid quenching. There is no chance of survival left for those products whose internal configurations fail in maximizing the rate constant for following rapid quenching. Only such an internal configuration that can be fastest in lowering its temperature as facing the rapid quenching while processing each of ligation and hydrolysis from within will win, and there is no chance left for the slower contenders.

Reaction kinetics is already selective internally in maximizing the rate constant for following rapid quenching, while the factor driving the internal selection is sudden temperature drops applied externally. Henceforth, once both the internal selection and the external driving factor are naturalized in an integrated manner, the outcome from the integration can be seen as a consequence of the selection of a natural origin even prior to the onset of Darwinian natural selection. A likely candidate for materializing pre-Darwinian natural selection on Earth could be chemical reactions riding on hydrothermal circulation of seawater through or near the hot vents in the ocean. Of course, the occurrence of hydrothermal circulation of seawater is exclusively of geological origin and totally external to biological processes and organizations. Nonetheless, chemical reactions riding on hydrothermal circulation of seawater, once happened to occur, could take advantage of pre-Darwinian natural selection.

What is specific to pre-Darwinian natural selection latent in chemical reactions riding on hydrothermal circulation of seawater is a frequent update of the reactants visiting the hot reaction spots. The reactants are only those products that could survive the rapid quenching to be experienced after visiting the hot spots the last time. It may look like a successive update of the reaction conditions in an increasingly specific manner progressively as repeating the visits, but no intelligence of external origin is involved. At the same time, how the surviving reaction products would manage the internal regulation of both ligation and hydrolysis could not be directly accessible to the external observer. Concrete factual aspects of pre-Darwinian natural selection associated with chemical reactions riding on hydrothermal circulation would have to be sought in the results of the corresponding experiments, while their actual objective and the likely target would also have to clearly be made as much as possible in advance.

One selective nature latent in the reaction solution of only monomers initially must be found in the selective scheme of the gradual buildup of oligomers through the internal regulation of both ligation and hydrolysis as repeating the cycle of heating and quenching. Further examination of the present conjecture on the selective elongation of oligomers requires consultation with a corresponding experiment. When a flow reactor simulating hydrothermal circulation of seawater equipped with rapid quenching from 250°C down to 0°C somewhere along the streamline was employed for studying elongation of glycine oligomers in the presence of copper ions, the elongation was found to proceed in the sequential order from ► [diketopiperazine](#), diglycine, tetraglycine, to hexaglycine along the time course of development (Imai et al. 1999). Both triglycine and pentaglycine were not identified. The result reveals that the chain elongation could be due largely to aminolysis of diketopiperazine. The elongation was already selective in eliminating the cases of adding monomeric glycine one by one onto the then surviving oligoglycine.

Polymerization of monomers through elongation of oligomers proceeding under the influence

of rapid quenching can be history-dependent and evolutionary in demonstrating a pre-Darwinian natural selection. The hydrothermal environments on the seafloor in the ocean must have been pivotal in keeping the cradle for nurturing the operation of pre-Darwinian natural selection for synthesizing polymers of prebiotic significance.

PCR

Definition

Polymerase chain reaction or PCR is an artificial method for the amplification of double-stranded ► [DNA](#) – dsDNA – fragments based on the action of a thermostable DNA polymerase. It allows for the quick, reliable, and highly sensitive in vitro amplification of DNA from any source. The reaction consists of a series of replication cycles of three successive phases: (1) *denaturation* of the parental dsDNA into two complementary single-stranded – ssDNA – molecules; (2) *annealing* or hybridization of two short ssDNA primers with their respective complementary region in each ssDNA strain; and (3) *elongation* or DNA replication of each primer-bound ssDNA strain by the DNA polymerase, rendering two identical dsDNA molecules. Cycles of exponential amplification are repeated 30–40 times, resulting in over a million-fold amplification of the initial material.

Overview

Since its invention in the mid 1980s (Saiki et al. [1985](#); Mullis and Faloona [1987](#)), PCR has revolutionized genetics and molecular biology by permitting rapid amplification of DNA of any length – up to 50,000 nucleotides, nt – and sequence. A general requirement for the target DNA is that the flanking sequences at both ends of the fragment to be amplified must be known, thus allowing the use of two short – usually 15–30 nt long – DNA primers complementary to them during the annealing phase of each cycle. Currently, PCR is a routine protocol that only requires the target DNA, forward and reverse primers, a thermostable DNA polymerase, triphosphate deoxynucleotides as monomers, and a buffer that provides the required pH and salts for the reaction.

Once the reaction mixture is prepared, PCR is performed automatically in equipment called thermocyclers or thermal cyclers, taking 2–3 h for completion. Alternatively, advances in microfluidics and microchip technology allow 20 cycles

of PCR to be completed in only 90 s (Innis et al. 1990; Sambrook and Russell 2001). The detection and characterization of the amplified product is done after the last cycle in traditional PCR. In turn, real-time quantitative PCR combines amplification and detection in a single tube, thus measuring the amount of amplified DNA at each cycle (Higuchi et al. 1992; Smith and Osborn 2009).

PCR amplification of DNA can be accomplished by DNA polymerases from different thermophilic microorganisms, able to withstand the high temperature – usually 90–94 °C – used during the denaturation phase of each cycle. The optimal DNA polymerization temperature of these enzymes – and thus the selected elongation temperature in PCR – is 68–74 °C. Different DNA polymerases show differences in efficiency (yield of DNA amplification per unit of the enzyme or per cycle), processivity (average length of the DNA amplified), and fidelity (frequency of polymerase-induced errors). These parameters also depend on the PCR conditions. The most widely used enzyme has been ► *Taq polymerase*, purified from the thermophilic bacterium *Thermus aquaticus*. Nevertheless, the high error rate associated with the DNA replication performed by this enzyme has encouraged the use of high fidelity DNA polymerases of some hyperthermophilic archaea such as: *Vent*, from *Thermococcus litoralis*; *Pfu*, from *Pyrococcus furiosus*; *Pwo*, from *Pyrococcus woesei*; and mixtures or genetically engineered versions of them (Pavlov et al. 2004; Lewin 2008).

Different experimental variants of PCR technology currently used include reverse transcription followed by PCR (also called RT-PCR), double or nested PCR, asymmetric PCR, multiplex PCR, mutagenic PCR, random PCR, inverse PCR, and ligation-mediated PCR (Innis et al. 1990; Lewin 2008). All of them enjoy an increasing applicability in different fields of biology and medicine.

Definition

A polynucleotide is a repeating polymer composed of ► [nucleotide](#) monomers covalently bonded via phosphodiester bonds. DNA and RNA are examples of polynucleotides. The chain length at which an oligonucleotide becomes a polynucleotide is somewhat arbitrary, but some biochemists define the transition as occurring at lengths of 13 or more nucleotide residues.

Comet · Distributed source · Formaldehyde · Polymer

Synonyms

[Paraformaldehyde](#); POM

Definition

Polyoxymethylenes (POM) are polymers of formaldehyde. They can exist either in cyclic (trioxane $C_3O_3H_6$ and tetroxane $C_4O_4H_8$) or linear form. The latter includes a wide range of chain lengths with the formula $(HO(CH_2O)_nH)$. The low molecular weight polymers (typically ranging from 10 to 100 monomers units) are commonly known as paraformaldehyde and are readily thermally degraded into pure formaldehyde. They are used in chemistry as a source of pure H_2CO . High molecular weight polymers (a few hundreds to a few thousands monomer units) are extensively used in the plastics industry for their remarkable mechanical properties (Walker 1964). POM could have had a key role in prebiotic chemistry as a source of concentrated formaldehyde for the ► [formose reaction](#).

Overview

The presence of polyoxymethylene in comets has often been proposed to interpret various puzzling

observations in their comae, although it has not been directly unambiguously detected yet. The presence of polyoxymethylene in the interstellar medium has been discussed since the middle of the 1970s. However, no clear observational evidence of its presence has ever been reported, either because it is not synthesized in such environments or because its detection is compromised by the presence of silicates, the infrared signatures of which are similar to those of POM. In 1987, its detection was reported in the comet 1P/Halley by mass spectrometry (Huebner 1987). However, a few years later, it was demonstrated that the mass spectral characteristics attributed to POM could also be the signature of a complex mixture of organic compounds (Mitchell et al. 1992). This does not rule out the presence of POM, but makes its detection ambiguous. In the early twenty-first century, it was demonstrated that the distribution of formaldehyde in the comae of comets 1P/Halley and C/1995 O1 (Hale Bopp), which could not be explained by a direct production of formaldehyde from the nucleus, could be explained by the presence of a few mass percent of POM in the nucleus of the comet, ejected on grains in the coma, and then slowly degraded into gaseous formaldehyde by photo and thermal degradation processes. POM would then be the parent compound of the so-called distributed source of formaldehyde in comets (Cottin et al. 2004; Fray et al. 2006). Though this is not a direct detection, this demonstration strengthens the probability of the presence of this polymer in some comets in the form of relatively small polymeric units similar to laboratory paraformaldehyde. This idea is backed by laboratory experiments showing that POM can be synthesized in cometary ice analogs under certain conditions (Schutte et al. 1993; Duvernay et al. 2014). The presence of POM at the surface of the nucleus of comet ► [67P/Churyumov–Gerasimenko](#) has been proposed to interpret a pattern of peaks in mass spectra measured by the Ptolemy instrument in the *Philae* lander (Wright et al. 2015). However, its presence could not be confirmed or quantified by other instruments either in the lander or the main spacecraft.

If POM is present in comets, it could have played an essential role in synthesizing sugars on the primitive Earth bombarded by comets, being a

source of concentrated formaldehyde for the formose reaction.

Polypeptide

Shin Miyakawa

6-1-7 Minami Hatsutomi, Kamagaya, Japan

Definition

A polypeptide is a ► [polymer](#) formed by the covalent bonding of a certain number of amino acids. The

exact lengths for peptides, oligopeptides, polypeptides, and ► [proteins](#) are not clearly defined; however, oligopeptides < polypeptides < proteins. Most naturally occurring polypeptides are composed of the 20 proteinogenic L-amino acids, although many microbial polypeptides contain unusual noncoded amino acids, such as ► [sarcosine](#), β -amino acids, and D-amino acids. Some examples of biological peptides are calcitonin (32 amino acid long) and adrenocorticotrophic hormone (39 amino acid long).

Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

Porphyrins are heterocyclic organic macrocycles composed of four modified pyrrole rings connected by their α -carbon atoms via methine [-CH=] linkages. Porphyrins are aromatic and thus obey Hückel's $4n + 2 \pi$ electron rule. Porphyrins are highly conjugated and have very intense absorption in the visible region and may be deeply colored. The name porphyrin derives from the Greek word for purple. Porphyrins are the conjugate acids of ligands that form complexes by binding metal ions, which are usually in the +2 or +3 oxidation state. Some porphyrins, such as ► [heme](#), coordinate iron; other porphyrins chelate cobalt, magnesium, manganese, or nickel. Porphyrin-like compounds have been reported in meteorites, and a prebiotic synthesis has been proposed starting from pyrroles and aldehydes. Acidic conditions are required for this synthesis.

History

F. M. Johnson proposed in the 1970s that porphyrins were the carriers of the ► [diffuse interstellar bands](#). This proposal has not been supported by subsequent observations, although large organic molecules remain prime candidates for the still-unidentified carriers of these absorption features in stellar spectra.

³Center for Chemical Evolution, Georgia Institute of Technology, Atlanta, GA, USA

⁴Maison des Géosciences, LGCA, Université J. Fourier, St-Martin d'Hères, France

A postimpact plume is the cloud of gas and fine debris ejected by the impacts of ► [comets](#) and ► [meteorites](#) on the surfaces or atmospheres of

planetary bodies. One example is the plume released by the impact of fragments of the comet Shoemaker-Levy on Jupiter; another is that produced by the impact of an artificial satellite and booster rocket on the moon. Spectral analysis of plumes provides information about the composition at the surface of the target and of the impactor. Such plumes could also be responsible for significant atmospheric chemical synthesis during the early formation of planets.

Poynting-Robertson Drag

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Definition

A particle in orbit around a star absorbs stellar radiation and, assuming that it is rapidly rotating and hence has an isothermal surface, it reradiates energy isotropically in the particle's rest frame. Consequently, in the star's rest frame the particle radiates preferentially in the direction of its motion, so that it loses momentum, energy, and angular momentum, and thus spirals inward toward the star. This effect, the predominant perturbation on centimeter-sized particles in otherwise ► [Keplerian orbits](#) around a host star such as the Sun, is called Poynting-Robertson drag.

History

John Henry Poynting gave a classical physics description of this effect in 1903. In 1937, the more complete relativistic description was published by Howard Percy Robertson.

Definition

Prebiotic chemistry is the study of the abiotic synthesis of organic compounds that may have been necessary for the origin of life. Although many syntheses that are now considered to be likely prebiotic processes, such as the Strecker synthesis, were demonstrated in the nineteenth century, few experiments were conducted with the express intent of demonstrating how organic compounds could have formed in primitive environments until the 1950s, beginning with the work of Calvin and coworkers, but more notably by Stanley Miller. This remains an ongoing area of investigation.

Definition

Prebiotic phosphorylation is defined as the phosphorylation process of the nucleoside with a phosphate source to obtain a nucleotide in a prebiotically plausible routes for phosphorylation reactions.

Overview

Phosphorylation, a fundamental process for cellular growth and metabolic pathways (Xing et al. 2017), still remain argument of debate in prebiotic chemistry (Whicher et al. 2018). The attention has been focused on thermal conditions in the presence of various phosphorus reagents, such as ortho-phosphate (Osterberg and Orgel 1972; Chang et al. 1968; Yamagata et al. 1979), condensed phosphates (Schwarz and Ponnampertuma 1968), mineral phosphates (Mullen and Sutherland 2007), reduced phosphorus(III) compounds, and hydroxyapatite (Graaf et al. 1995). These reactions required the presence of catalysts and condensing agents to overcome the unfavorable activation energy in water. Vacuum ultraviolet (VUV) radiation and γ -radiation have been also reported as alternative energy sources

(Simakov and Kuzicheva 2005). In addition, the phosphorylation of adenosine in dry-film condition was described by using proton beam as energy source in the presence of sodium orthophosphate (Simakov et al. 2002). Similar results were obtained in real space experiments by satellite exposure of 2'-deoxy adenosine and NaH_2PO_4 (Kuzicheva and Simakov 1999). More recently, the role of deep eutectic solvents (Mamajanov et al. 2010; Gull et al. 2014; Welton 1999) and formamide (NH_2CHO) (Schoffstall 1976; Schoffstall et al. 1982) have been explored using ortho-phosphate and hydroxyapatite, NH_2CHO being able to solubilize both nucleosides and phosphorus reagents (Bizzarri et al. 2020). In this latter case, the process was activated by high energy proton beam irradiation mimicking the solar wind, the reaction being catalyzed by meteorites of the chondrite type. Reactive radical species have been identified as key intermediates of the process by computational studies. Thus, nucleotides may form in the same physical-chemical frame in which the formation of nucleic bases and nucleosides has been reported (Saladino et al. 2012; Saladino et al. 2017; Botta et al. 2017).

Definition

The most ancient traces of life dated from about 3.8 Ga. At that time, earth's surface was no longer the magma ocean that solidified 4.35 Ga ago or earlier. The primitive atmosphere inherited from the presolar nebula had disappeared, being replaced by a secondary atmosphere derived in part from the outgassing of the mantle and in part brought to the surface by extraterrestrial impactors and micrometeorites. This atmosphere was dominated not only by N₂ but also by several greenhouse gases such as carbon dioxide,

methane, and water vapor. The extent of surfaces covered by the oceans is unknown, but it can be postulated that – since the continents had not yet formed – the absence of the present-day bimodal distribution of elevations on earth caused water to cover most of the surface of the Archean earth. Undoubtedly, sedimentary rocks existed on earth since at least 3.85 Ga ago as shown by unambiguous sedimentary structures recorded from rocks in South Africa and Greenland. The temperature of the first oceans, however, has always been a subject of debate.

Overview

Cherts: Surviving Witnesses of Early Oceans

In the early 1950s, geochemists showed that the isotopic compositions of sedimentary rocks could be used to reconstruct the temperature of the oceans provided (1) the isotopic composition of seawater from which these rocks precipitated was known and (2) the geological evolution of these rocks had not altered their pristine isotopic compositions. These two points are key issues in reconstructing paleotemperatures in all types of environments and samples. Siliceous sediments (cherts) are common in the Precambrian. Since microplanktons (e.g., diatoms) able to fix soluble silica for building their skeletons did not exist in the Precambrian, it appears plausible that silica precipitated in Precambrian oceans in the form of amorphous silica deposited at the surface of the sediments. Today, this abiotic precipitation still exists in some rare terrestrial environments.

During burial of the marine sediments and subsequent diagenesis, the increase in pressure and temperature caused the progressive elimination of connate water along with mineralogical transformations of the silica. These transformations always involve the dissolution and reprecipitation of preexisting silica crystals. At the top of the sedimentary column, the first form of deposited silica is amorphous opal that is progressively transformed to microcrystalline silica (“opal-CT”), then to chalcedony and fibrous quartz. These transformations take place *in situ*, i.e., with almost no migration of silica; they are

caused by the large amount of liquid water trapped in the rocks and that is progressively expelled during the compaction of the sediment (e.g., Knauth 1992, 1994). We shall see below that this diagenetic evolution has important consequences on the significance of the temperature recorded by silica.

Compaction yields a rock exceptionally resistant to weathering in which the diffusion of water is negligible. The cryptocrystalline nature of chert, combined with its average ability to resist weathering, recrystallization, and metamorphism, has made it an ideal rock for the preservation of indigenous geochemical tracers such as isotopic compositions or the chemical fossils of early life (e.g., Hayes et al. 1983; Beaumont and Robert 1999). During metamorphism, fluids may nevertheless circulate along cracks or veins that are still clearly visible at the spatial resolution of tens of micrometers. However, the spatial isotopic and chemical exchange between the matrix and these veins is restricted to a few hundred microns. Unless a chert is extensively percolated by fluids during metamorphic events, their pristine geochemical compositions are preserved in their nanocrystalline silica matrix since deposition and crystallization. In this respect, cherts can be regarded as the best-preserved sedimentary rocks on earth.

Early studies reported oxygen isotopic compositions of cherts with the aim of reconstructing the temperature of the Archean oceans (e.g., Knauth and Epstein 1976; Knauth and Lowe 1978).

Measuring the Temperature of the Early Oceans

The oxygen isotopic composition of cherts shows a systematic decrease with geological time: the older the sample, the lower the isotope ratio ($\delta^{18}\text{O}$) (e.g., Knauth and Lowe 1978, 2003). Assuming that the isotopic composition of seawater did not change with time, this trend was interpreted as resulting from the progressive cooling of the oceans since 3.5 Ga. The partition of oxygen isotopes between water and silica was determined in the laboratory, and accordingly, a temperature of up to 80 °C was derived for the Archean oceans (Knauth and Lowe 1978). More

quantitatively, there is 1.6% more ^{18}O relative to ^{16}O at 20 °C than at 80 °C. The routine precision on the isotopic proportion being $\pm 0.02\%$, such a difference is easily detectable by modern isotope mass spectrometers. Precambrian cherts older than two billion years have oxygen isotopic compositions corresponding to crystallization temperatures higher than 40 °C. In contrast, Phanerozoic cherts have an isotopic composition corresponding to markedly cooler temperatures. It was thus concluded that the Precambrian oceans were hotter than today (Knauth and Lowe 1978, 2003).

This interpretation has been challenged. First, it was argued that the isotopic composition of oxygen in seawater from which these rocks precipitated has changed with time (Perry 1967) and therefore that the isotopic trend observed as a function of time reflects this evolution of the ocean but not its temperature (Kasting et al. 2006). The progressive reset in ^{18}O would have taken place during the interaction of seawater with the mantle via the intense hydrothermal circulation at mid-ocean ridges (Kasting et al. 2006). The half-life for recycling the entire oceans through these ridges is less than ten million years, and oxygen isotopes should be quickly equilibrated with the mantle with respect to the three billion years of ^{18}O evolution observed in cherts. However, no evidence of such change appears in the geological record.

Several studies have shown that Precambrian pillow lavas – i.e., volcanic lavas cooled rapidly in contact with seawater – did not show any specific isotopic compositions at their interface with seawater compared with their modern counterparts. In addition, in some cases, the phosphates contained in cherts have provided an independent estimate of the seawater isotopic composition that appears constant through geological times. Although a few theoretical models have reopened the issue of a possible drift of ^{18}O with time (Kasting et al. 2006), the general consensus is that the seawater isotopic composition remained constant within reasonable uncertainties, corresponding to a precision of ± 15 °C.

The second criticism of the thermometric interpretation deals with the problem of the

preservation of the chert isotopic compositions, by arguing that the older the cherts, the more disturbed are their compositions. This second aspect is more difficult to circumvent on the basis of oxygen isotopes and the petrology of cherts. Silicon isotopes shed new light on this issue.

Measuring the Silicon Isotope Composition of the Early Oceans

Based on the analyses of more than 100 chert samples covering the whole Precambrian period, it was shown that silicon and oxygen isotopic compositions exhibit some covariation (Robert and Chaussidon 2006), a priori unexpected since silicon isotopes are – unlike oxygen – insensitive to temperature. The alteration processes for these two chemical elements – through which isotopic resets may take place – are completely decoupled. Indeed, during alteration, the carrier of silicon is the dissolved silica whose concentration rarely exceeds 200 ppm, while the carrier of oxygen is the water itself. In addition, once under the form of silica, the isotopic exchange of silicon could occur only in solution via the dissolution – reprecipitation of silica. Consequently, in order for the relation between the isotopic compositions of silicon and oxygen to be maintained, secondary effects post-dating the chert formation must be limited. Some cherts, however, clearly show late disturbance in their oxygen isotopes with no counterpart for silicon (Marin-Carbonne et al. 2014).

These silicon and oxygen isotopic covariations are well accounted for by the solubility of silica in the oceans and hence are ultimately related to seawater temperature. The results of such a model are reported in Fig. 1 as variations in oceanic temperatures between 3.5 and 0.5 billion years. For samples younger than 0.5 billion years (arrow 1 on the Fig. 1), the silicon and oxygen isotopic covariation disappears, which indicates that silicon isotopes stop recording oceanic temperatures. This is attributed to the appearance of silica fixators in the oceans – siliceous planktons (diatoms) – that have maintained so far silica under saturation. In other terms, during the Phanerozoic, the concentration in silica dissolved in the ocean was no longer dictated by

Precambrian Oceans, Temperature of, Fig. 1 The temperature of the oceans is reconstructed from three independent proxies: (1) the solid line stands for oxygen isotopes (After Knauth and Lowe 2003); (2) the gray area stands for silicon isotopes (After Robert and Chaussidon 2006); and (3) the data points with error bars stand for the

elongation factors of a selection of proteins in microorganisms (After Gaucher et al. 2008). Arrows 1 and 2 designate (1) the emergence of silica-fixing organisms in oceans and (2) the oldest siliceous marine sediments found on earth, respectively. Time is in Ga

the temperature but by the metabolic activity of the plankton (De la Rocha et al. 1997). The oldest preserved cherts on earth (dated at 3.5 Ga; cf. 2 on Fig. 1) exhibit the lowest silicon and oxygen isotope ratios, corresponding to the highest oceanic temperatures.

Robustness and Limits of the Secular Oceanic Temperature Evolution Model

Following the publication where the covariations in silicon and oxygen isotopes in the Precambrian were interpreted as a seawater temperature evolution (Robert and Chaussidon 2006), the assumptions of this conjecture were re-questioned by several authors. These assumptions are (i) the seawater $\delta^{18}\text{O}$ did not evolve during these last 3.0 billions years (addressed by Jaffrés et al. (2007)) and (ii) the temperature of crystallization of silica is registered by cherts with limited post-depositional alteration (addressed by Sengupta and Pack (2018)).

- (i) On the basis of a thorough review of existing data on this question, Jaffrés et al. (2007) constructed a detailed model accounting for the secular increase of marine carbonates with decreasing age. The carbonate trend is parallel to the one defined by cherts but yield higher seawater temperatures at the Archean (up to 100 °C). In this model describing the geological water cycle, the seawater $\delta^{18}\text{O}$ increases by $\approx 13\text{‰}$ over a period of 3.4 Ga. This secular increase of $\delta^{18}\text{O}$ seawater values would result from both an enhanced weathering on the newly emerged continents as well as the diminishing impact of the high-temperature alteration taking place at the mid-ocean ridges. This increase in seawater $\delta^{18}\text{O}$ implies that the Precambrian oceans temperature were similar to that of the present day.
- (ii) On the contrary, Sengupta and Pack (2018), using the combined $\delta^{17}\text{O}/\delta^{18}\text{O}$ variations in

cherts, argued that the seawater $\delta^{18}\text{O}$ was constant in time but that the evolution in chert $\delta^{18}\text{O}$ values during the Precambrian is explained by the diagenesis of silica involving low $\delta^{18}\text{O}$ meteoric water. Accordingly, the Precambrian silica would have precipitated in cool oceans. Note that Bindeman et al. (2018), using the same $\delta^{17}\text{O}/\delta^{18}\text{O}$ criteria on shales, reconstructed a Precambrian temperature evolution similar to that proposed in the Fig. 1.

In summary, both approaches, although somewhat contradictory, conclude that there is no natural evidence for an oceanic temperature change during geological times.

These two arguments have been examined with two distinct analytical protocols. For (i), the $\delta^{18}\text{O}$ of the kerogen embedded in Precambrian cherts has been measured and for (ii) the isotopic homogeneity of silica in cherts has been determined at a 20 μm spatial resolution.

- (i) Precambrian kerogen can only be derived from marine plankton. Consequently, oxygen atoms in this biological organic matter came from water. The isotopic composition of biomolecules is largely determined by metabolic exchange between living organisms and their environment and is almost insensitive to temperature (within 2–3‰ in $\delta^{18}\text{O}$). The $\delta^{18}\text{O}$ of marine organisms define an isotopic fractionation factor between water and organic oxygen of $+25 \pm 5\%$. Tartèse et al. (2018) show that $\delta^{18}\text{O}$ in the Precambrian kerogen embedded in cherts has a constant value of $+20 \pm 4\%$. The difference between living organism and their remnants, i.e., between $+25\%$ and $+20\%$, is likely caused by an isotopic evolution of the insoluble organic matter during its diagenetic evolution in cherts. Nevertheless, this study indicates that the seawater $\delta^{18}\text{O}$ value was constant during geological times within $\pm 4\%$. Propagating $\pm 4\%$ on the temperature of the precipitation of silica gives $\pm 20^\circ\text{C}$.
- (ii) Marin-Carbonne et al. (2010, 2014) have shown that the oxygen isotopic compositions are highly heterogeneous at a micrometric

scale. The $\delta^{18}\text{O}$ variations can reach 6.6‰ at a 20 μm scale. During the removal of water from the siliceous sediment, microdomains grown up and prevent a large-scale circulation of water during the final compaction of the rock. Each microdomain had its own isotopic evolution governed by a close reservoir water–silica fractionation. This isotopic heterogeneity (6.6‰) likely reflects this progressive closure. This observation contravenes models where the circulation of meteoric water would have lowered the $\delta^{18}\text{O}$ of the silica. Any water circulation would have erased such isotopic heterogeneity. Note that Phanerozoic cherts that precipitated from large-scale water circulation in their parent carbonate rocks do not exhibit such an isotopic heterogeneity.

The discovery of this isotopic heterogeneity has shown that the bulk $\delta^{18}\text{O}$ of chert cannot be taken as a face value to derive the precipitation temperature of silica. A correct thermometric interpretation of the chert oxygen isotopic compositions requires an assessment of the extent of diagenetic alteration. Although such an effect cannot erase the relative variations reported in Fig. 1, a Rayleigh distillation model calculated to account for the $\delta^{18}\text{O}$ micrometer distribution suggests that the seawater temperatures could be as lower as 10–15 $^\circ\text{C}$ compared to the temperatures reported in Fig. 1.

Interestingly, this model was independently supported by biological studies on proteins in which the elongation factors can be scaled to estimate the age of the last mutation responsible for this elongation (Gaucher et al. 2008). The timescale of resurrected proteins provides a palaeotemperature proxy for the environments that hosted life from 3.5 to 0.5 billion years ago. The thermostability of several phylogenetically dispersed ancestral elongation factors suggests that these environments cooled progressively during the last 3.5 billion years. It seems that ancient life has continually adapted to changes in environmental temperatures throughout its evolutionary history. The corresponding variations in temperature versus time are reported in Fig. 1 (data points with error bars) for comparison with

isotopic temperatures. The resemblances in the trends are quite compelling.

A general consensus seems now to emerge: as suggested by Jaffrés et al. (2007) and Sengupta and Pack (2018), variations in the seawater $\delta^{18}\text{O}$ and the contribution of low $\delta^{18}\text{O}$ water in diagenesis are expected but their magnitudes do not erase the temperature signal. From all these observations, the suggestion that early Precambrian oceans were several tens of degrees warmer than the modern ocean has definitively gained some acceptance. Nevertheless, the exact significance of this temperature remains an open issue.

Precession

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

Precession is the change in the orientation of the rotational axis of an astronomical body, such as a star or a planet, under the gravitational forces due

to one or several nearby massive bodies. The change is slow and continuous and the axis, like in a wobbling top, describes a cone.

Earth's precession of the equinoxes is one of the best-studied effects of this kind: it results from the combined action of the Sun and the Moon on the equatorial bulge of the Earth, the bulge itself being created by the centrifugal force induced by the rotation. The Earth ► [polar axis](#) traces a cone of half-angle 23.4° in about 26,000 years.

Exoplanets as well are capable of precession, and it is not unlikely that the effect could be observed in some particular cases.

Precursor

Kensei Kobayashi
Yokohama National University,
Yokohama, Japan

Synonyms

[Parent molecule \(ion, species\)](#)

Definition

When a compound A gives rise to another compound B after some simple chemical reaction, A is called a precursor of B. For example, aminoacetonitrile is a precursor of glycine since hydrolysis of aminoacetonitrile gives glycine. This term is also used in astronomy (e.g., chemical species found in cometary nuclei are precursors of the species in cometary comae) and in biology (e.g., metabolic pathways).

Predissociation

Stefanie N. Milam
Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

Predissociation is the break-up of a molecule in an excited state without the emission of radiation. Predissociation occurs when there is a radiationless transition from the excited energy level (electronic, vibrational, or rotational) to an overlapping dissociation continuum.

Primordial Heat

Doris Breuer
 German Aerospace Center (DLR), Institute of
 Planetary Research, Berlin, Germany

Definition

Primordial heat is the internal heat energy accumulated by dissipation in a ► [planet](#) during its first few million years of evolution. The main contributions to the primordial heat are accretional energy – the energy deposited by infalling ► [planetesimals](#) – and ► [differentiation](#) energy. The latter is mainly released by core formation and is basically potential energy that is dissipated upon formation of a gravitationally stable layering of the planet. In addition to the primordial heat, the planet’s internal heat source is mainly provided by the radioactive decay of long-lived unstable isotopes such as ²³⁸U, ²³⁵U, ²³²Th, and ⁴⁰K and by latent heat.

Primordial Soup

Antonio Lazcano

Facultad de Ciencias, UNAM, Cd. Universitaria, Mexico, DF, Mexico

Keywords

Abiotic organic synthesis · Oparin-Haldane · Origin of life · Primordial heterotrophs

Synonyms

[Prebiotic soup](#); [Primitive broth](#)

Definition

The primordial soup is a generic term that describes the aqueous solution of organic compounds that accumulated in primitive water bodies of the early Earth as a result of endogenous abiotic syntheses and the extraterrestrial delivery by cometary and meteoritic collisions, and from which some have assumed that the first living systems evolved.

Overview

The term “primordial soup” and its synonyms are linked to the proposal of the heterotrophic theory

of the origin of life, which was suggested independently in the 1920s by Alexander I. Oparin, John B. S. Haldane, and few others. Based on the simplicity and ubiquity of fermentative reactions, Oparin and Haldane proposed that the first organisms must have been heterotrophic bacteria that could not make their own food but obtained organic material present in the primitive milieu. In order to support his proposal, Oparin appealed not only to astronomical observations that had shown that hydrocarbons and other organic material were present in meteorites and cometary nuclei but also to the nineteenth-century experimental syntheses of organic molecules by Wohler, Butlerow, and Mendeleyev, among others (Lazcano 2010a).

Similar ideas were being developed independently at the same time by other researchers. Like Oparin, the British biochemist and geneticist John B. S. Haldane argued in 1929 that the origin of life had been preceded by the synthesis of organic compounds. Based on experiments by E. C. C. Baly, an English chemist who had reported the formation of amino acids and sugars as a result of the UV irradiation of a solution of CO₂ in water, Haldane suggested that the absence of oxygen in a CO₂-rich primitive atmosphere led to the synthesis of organic compounds and their accumulation in the primitive waters of the Earth, which he wrote had “the consistency of hot dilute soup.” The discovery of phages led Haldane to argue that viruses represented an intermediate step in the transition from the prebiotic broth to the first heterotrophic cells (Farley 1977; Lazcano 2010a).

A Darwinian Warm Little Pond

In 1871, Charles Darwin mailed a letter to his close friend Joseph Dalton Hooker in which he mentioned Pasteur’s work on the absence of spontaneous generation and added that “It is often said that all the conditions for the first production of a living organism are now present, which could ever have been present. But if (and oh what a big if) we could conceive, in some warm little pond with all sorts of ammonia and phosphoric salts, light, heat, electricity, and c. present, that a protein compound was chemically formed, ready to undergo still more complex changes, at the present day such matter would be instantly devoured,

or absorbed, which would not have been the case before living creatures were formed.”

However, the “hot dilute soup” concept formulated by Haldane developed independently of Darwin’s warm little pond. During the first part of the twentieth century, most authors assumed, at least implicitly, that the origin of life had taken place in an aqueous environment. When Winslow Herschel discussed the consistency of colloids, which by then were assumed to explain many of the properties of protoplasm (Podolsky 1996), he wrote that “How many factors determine consistency is a matter of controversy, but the colloquial meaning of the word is well understood and may be illustrated by the description, from a recent novel, of ‘Flanders mud after a thaw’. As the flow increased, the side of the trenches began to fall in; the earth thus mixed with the water thickened it to a consistency which might be liked to a very rich soup” (Herschel 1926).

There is nothing that suggests that Herschel, Haldane, or Oparin had read Darwin’s remarks about the origin of life and the warm little pond. Darwin’s letter was included by his son Francis as a footnote in the 3rd volume of his father’s book *Life and Letters* published in 1887, but it was not until 1969 that Melvin Calvin published it in his book on chemical evolution (Calvin 1969), calling it to the attention of the origins-of-life community (Peretó et al. 2009). By then, the concept of a prebiotic broth and a heterotrophic origin of life, which had been developed by Oparin and Haldane within the framework of an evolutionary perspective, had gained considerable support from the development of a multidisciplinary research program on the emergence of the first living systems.

Defining the Soup

The proposal that life was the outcome of prebiotic chemistry and the evolution of precellular systems was further elaborated and refined by Oparin in a more extensive book that was published in Russian in 1936 and translated 2 years later into English (Oparin 1938). In his new book, Oparin suggested that the primitive Earth was a highly reducing milieu in which iron carbides of geological origin would react with steam to form ► [hydrocarbons](#). Their oxidation

would yield alcohols, ketones, aldehydes, etc., that would then react with ► [ammonia](#) to form amines, amides, and ammonium salts. The resulting protein-like compounds and other molecules would form a hot dilute soup, in which they would aggregate to form colloidal systems such as coacervates, from which the first heterotrophic microbes evolved. Others, like John D. Bernal, argued that the compounds were concentrated on the surfaces of minerals like clays, where the higher density would favor their chemical interaction (Bernal 1944).

Experimental evidence in support of Oparin’s proposal came first from Harold C. Urey’s laboratory, at the University of Chicago, who had considered the origin of life in the context of his proposal of a highly reducing terrestrial atmosphere (Urey 1952). The first successful prebiotic amino acid synthesis was carried out with an electric discharge and a strongly reducing model atmosphere of CH_4 , NH_3 , H_2O , and H_2 (Miller 1953). The result of this experiment was a significant yield of a racemic mixture of amino acids, together with hydroxy acids, short aliphatic acids, and urea. One of the surprising results of this experiment was that the products were not a random mixture of organic compounds; rather, a relatively small number of compounds, most of which were of biochemical significance, were produced in substantial yield. The Miller-Urey experiment marked not only a new epoch in the study of the origin of life but also led to surprisingly rapid acceptance by the public of both the heterotrophic theory and the idea of a primitive soup (Bada and Lazcano 2003).

Was There a Primitive Soup?

Although it is generally agreed that free oxygen was absent from the primitive Earth, there is no agreement on the composition of the primitive atmosphere; opinions vary from strongly reducing ($\text{CH}_4 + \text{NH}_3 + \text{H}_2\text{O}$, or $\text{CO}_2 + \text{H}_2 + \text{N}_2 + \text{H}_2\text{O}$) to neutral ($\text{CO}_2 + \text{N}_2 + \text{H}_2\text{O}$). In general, non-reducing atmospheric models were favored by planetary scientists, while prebiotic chemists leant toward more reducing conditions, under which the abiotic syntheses of amino acids, purines, pyrimidines, and other compounds are very efficient. Prior to the recognition that organic

compounds can be synthesized under the neutral conditions of a CO₂-rich atmosphere (Cleaves et al. 2008), the difficulties involved with the endogenous synthesis of amino acids and nucleobases have led to the development of alternatives.

In the early 1990s, Chyba and Sagan reanalyzed Oró's 1961 proposal on the role of cometary nuclei as sources of volatiles to the primitive Earth and, based on the chemical composition of carbonaceous meteorites, proposed that the exogenous delivery of organic matter by asteroids, comets, and interplanetary dust particles could have played a significant role in forming the primitive soup, by seeding the early Earth with the compounds necessary for the origin of life (Chyba and Sagan 1992). On the other hand, proponents of an autotrophic theory of the origin of life (Wächtershäuser 1988) have dismissed the role of prebiotic synthesis and accumulation of organic compounds. However, since the FeS/H₂S combination is a strong reducing agent that has been shown to reduce nitrate and acetylene, induce the formation of peptide bonds between amino acids activated with carbon monoxide and (Ni, Fe)S (Maden 1995; Huber and Wächtershäuser 1998), and catalyze the synthesis of acetic acid and pyruvic acid from CO under simulated hydrothermal conditions (Huber and Wächtershäuser 1997; Cody et al. 2000), the role of Fe/S minerals is also compatible with a more general, modified model of the primitive soup in which pyrite formation is recognized as an important source of electrons for the reduction of organic compounds (Bada and Lazcano 2002).

There has been no shortage of discussion about how the formation of the primitive soup took place. However, it is likely that no single mechanism can account for the wide range of organic compounds that may have accumulated on the primitive Earth and that the prebiotic soup was formed by contributions from endogenous syntheses in a reducing atmosphere, metal sulfide-mediated synthesis in deep-sea vents, and exogenous sources such as comets, meteorites, and interplanetary dust. This eclectic view does not beg the issue of the relative significance of the

different sources of organic compounds, but it simply recognizes the wide variety of potential sources of organic compounds, the raw material required for the emergence of life (Bada and Lazcano 2009; Lazcano 2010b).

The Prebiotic Broth: A Risky Metaphor?

Synonymous terms like "primitive soup," "primordial broth," or "Darwin's warm little pond" have led in some cases to major misunderstandings, including the simplistic image of a world-wide ocean, rich in self-replicating molecules and accompanied by all sorts of biochemical monomers. However, nowadays, it refers to parts of the prebiotic environment where the accumulation and interaction of the products of abiotic synthesis may have taken place, including oceanic sediments, intertidal zones, shallow ponds, membrane-bound systems, freshwater lakes, and lagoons undergoing wet-and-dry cycles. The soup may have been semifrozen, and glacial ponds where evaporation, eutectic separations, or other physicochemical mechanisms, such as the adherence of biochemical monomers to active surfaces, could have raised local concentrations and promoted polymerization (Bada and Lazcano 2009).

Given adequate expertise and experimental conditions, it is possible to synthesize almost any organic molecule. However, the fact that a number of molecular components of contemporary cells can be formed nonenzymatically in the laboratory does not necessarily mean that they were also essential for the origin of life or that they were available in the prebiotic environment. The primitive soup must have been a bewildering organic chemical wonderland, but it could not include all the compounds or molecular structures found today in even the seemingly most primitive prokaryotes. It is possible that some compounds, including perhaps RNA itself, may not have been synthesized prebiotically, so their occurrence in living systems may have been the result of early metabolic syntheses.

During the past few years, laboratory simulations of prebiotic synthesis have been developing models of specific detailed environments, including those that may have been provided by the

surface of clays, small volcanic ponds, and liposomes. Our ideas on the prebiotic synthesis of organic compounds are based largely on experiments in model system, and the evidence suggests that the remarkable coincidence between the molecular constituents of living organisms and those synthesized in prebiotic experiments is too striking to be fortuitous. The robustness of this type of chemistry is supported by the occurrence of many of these biochemical compounds in the 4.5-billion-year-old Murchison carbonaceous chondrite and other carbon-rich meteorites, suggesting that similar synthesis took place on the primitive Earth (Miller and Lazcano 2002).

Conclusions

How the first life evolved is not known, but analysis of carbonaceous chondrites and the laboratory simulations of the primitive Earth suggest that prior to the emergence of the first living systems, the prebiotic environment was endowed with (1) a large suite of organic compounds of biochemical significance; (2) many organic and inorganic catalysts (such as ► [cyanamide](#), metallic ions, sulfur-rich minerals and clays); (3) purines and pyrimidines, that is, the potential for template-dependent polymerization reactions; (4) membrane-forming compounds; and (5) the availability of many possible sources of carbon and nitrogen for primordial heterotrophs. Once life appeared and biosynthetic pathways developed, the reservoir of organic material present on the Earth then shifted from one initially characterized by compounds of abiotic origin to one made up entirely of biologically derived components (Lazcano 2010b).

The existence of different abiotic mechanisms by which biochemical monomers can be synthesized under plausible prebiotic conditions is well established. Of course, not all prebiotic pathways are equally efficient, but the wide range of experimental conditions under which organic compounds can be synthesized demonstrates that prebiotic syntheses of the building blocks of life are robust, that is, the abiotic reactions leading to

them do not take place under a narrow range defined by highly selective reaction conditions, but rather under a wide variety of experimental settings. Like other scientific metaphors, the term “primitive soup” is risky but useful and has become a part of popular lore. For all the uncertainties surrounding the emergence of life, it appears that the formation of the prebiotic soup is one of the most firmly established events that took place in the primitive Earth.

Principle of Plenitude

David Dunér

Lund University, Lund, Sweden

Keywords

Cosmology · History of Science · Philosophy of Science · Possibility

Synonyms

Fullness of being; *Plenum formarum*

Definition

The Principle of Plenitude suggests that every genuine possibility is realized or actualized. As an argument in astrobiology, this means that if an environment has the right conditions for life, one concludes that it also harbors life.

History

The Principle of Plenitude or “fullness of being” was coined by the historian of ideas, Arthur O. Lovejoy. In his classic volume *The Great Chain of Being* (1936) he explained the Principle of Plenitude as: “no genuine potentiality of being can remain unfulfilled, that the extent and abundance of the creation must be as great as the possibility of existence and commensurate with the productive capacity of a ‘perfect’ an inexhaustible Source, and that the world is the better, the more things it contains.” The universe is a *plenum formarum*, that is, all possible forms of existence have become realized. The principle has commonly been assumed in Western science and philosophy, from Plato, Aristotle, and Plotinus in the Antiquity, through medieval philosophers, to Spinoza, Leibniz, and the Enlightenment. In his dialogue, *Timaeus* from c. 360 BCE, Plato explained how the demiurge created a perfected world, and thus created all imaginable

possibilities (Plato 1989). The Principle of Plenitude was further more in line with a Christian worldview. God had, according to Christian theologians, made the creation of the world complete. All possibilities have actually been created.

The argument from the Principle of Plenitude, as Lovejoy claimed, lies behind much of the plurality of world debate up to the nineteenth century (Dick 1982; Crowe 1986, 2008; Crowe and Dowd 2013). In *De rerum natura* (On the Nature of Things) from the first century BCE, Lucretius proclaimed in an argument from plenitude: “when abundant matter is ready, when space is to hand, and no thing and no cause hinders, things must assuredly be done and completed” (Lucretius 2004). Giordano Bruno argued, in *De l’infinito, universo et mondi* (On the Infinite, Universe and Worlds, 1584), from the Principle of Plenitude when he supposed the idea of the plurality of worlds. Divine power cannot remain idle, and divine goodness must be infinitely diffused. Immanuel Kant wrote in *Allgemeine Naturgeschichte und Theorie des Himmels* (Universal Natural History and Theory of the Heavens, 1755): “Now, it would be senseless to set Godhead in motion with an infinitely small part of his creative ability and to imagine his infinite force, the wealth of a true inexhaustibility of nature and worlds to be inactive and locked up in an eternal absence of exercise.” Following the Principle of Plenitude, Kant says that creation rather ought to be a witness of this limitless power, an infinite manifestation of divine attributes. Johann Heinrich Lambert concluded in his *Cosmologische Briefe* (1761) from the Principle of Plenitude that other worlds must be inhabited. He asks: “Could the world be the effect of an infinitely active Creator, unless in every part of it life and activity, thoughts and desires, were found in the creatures? Could I conceive its perfection to consist in a continuous and inexhaustible diversification of similarities, and yet leave in it vacant places where there were no parts of a whole which should be infinitely complete? Such gaps I could not admit; and I had no hesitation in filling every solar system with habitable globes, so far as the admirable order which has been given to their course permits.”

Overview

The Principle of Plenitude was commonly used together with the Copernican Principle, stating that Earth has no privileged position in the universe. Implicit in the plenitude of the world was also the conception of continuity, a Chain of Being, from the simplest non-living matter to the most complex forms of life. Many proponents of the idea of a plurality of inhabited worlds explicitly started from the theological assumptions behind the Principle of Plenitude. If the universe was created by an omnipotent God, one concluded that this infinitely wise Creator also indeed created all possible things, because he was able to do it, and because one assumed that a richer and fuller creation is better than a poorer one. If life is something intrinsically good, a benevolent God must have filled the entire universe with life. This omnipotent and benevolent God would not have restricted himself and delimited life to just one minuscule place in the universe, our Earth. If other planets or stellar systems were devoid of life that would entail that God had wasted his creative power and had made desolate worlds to no use for any sentient being. The Principle of Plenitude, in other words, says that the universe ought to be as rich as possible. The Principle then implies that, because living things best demonstrate the richness of creation, life must be plentiful throughout the universe.

The Principle of Plenitude has historically been very influential in the debate concerning the existence of extraterrestrial life. But it is invoked implicitly or explicitly even today. Since the first confirmed discovery of exoplanets in 1995, the number of planets around normal Sun-like stars has turned out to be abundant. From an argument based on the Principle of Plenitude it seems tempting to conclude from this possible abundance of candidates for living planets that there must also exist life elsewhere in the universe. If the right conditions are in place, then the laws of nature would inevitably lead to the emergence of life. The Principle of Plenitude thus reminds of the principle of sufficient reason, which states that everything has a sufficient reason, cause, or explanation for being or not being. In this context,

plenitude means that if there is no sufficient reason for something not to be (or in other words, if it is indeed possible), then it exists. But a possibility is not a proof. What is possible is not always realized. Logically speaking, the Principle of Plenitude is not a valid argument. The right conditions for life do not entail that the actual environment also harbors life. It is a possibility, maybe a probability, and could in that respect function as a heuristic starting point for searching for extra-terrestrial life. But it is not a proof of life.

Definition

Prions are ► [protein](#)-based elements of infection and inheritance. Prions are made by alternate protein conformations that by acting as templates propagate their conformations to the precursor proteins. In general, this propagative state is an insoluble polymer, rich in tightly packed β -sheets and displaying amyloid staining features. This state is not structurally unique but polymorphic allowing strains. The protein undergoing prion conversion loses its normal function and acquires the ability to transform the precursor into its like. This protein conformational code provides physiological switches for fast environmental adaptation and underlies the spread of the mammalian neurodegenerative diseases known as transmissible spongiform encephalopathies.

History

The unique inactivation pattern displayed by the infectious agent causing scrapie reported by Alper et al. (1967) prompted Griffith (1967) to propose the “protein-only” hypothesis to explain a nucleic

acid-free information flow. This hypothesis considered mechanisms by which a protein could display replicative properties, as a catalyzed conformation and/or aggregation change. On the basis of the purification of the infectious agent causing scrapie, Prusiner (1982) coined the terms prion and PrP to refer to the proteinaceous infectious particle and the component protein, respectively. Since then, PrP prion properties have been ascribed to a conformational change from a normal cellular form (PrP^C) to a propagative form (PrP^{Sc}) that causes disease by converting the membrane-bound cellular form into its like. Whereas PrP^C is soluble and easily degraded by proteinase K, PrP^{Sc} is rich in β -sheets and aggregates into fibrils after proteinase K digestion (Prusiner 1998). While the essentiality of PrP^C for the prion infectivity, the propagative nature of PrP^{Sc} conformation, and its multiplicity have been demonstrated, the infectivity synthesized with pure protein polymers still provokes controversy by virtue of its low efficiency or by the requirement of effectors (Deleault et al. 2007; Aguzzi and Calella 2009; Colby et al. 2010; Makarava et al. 2010). Based on genetic observations, Wickner (1994) generalized the prion concept. Since then, an increasing number of yeast and fungi proteins exhibiting prion behaviors have been described. In fact, most of the compelling evidences for the prion concept have been established using these models. Of them, the direct demonstration of the infectious activity of a pure protein in its prion form was provided by [Het-s] prion (Maddelein et al. 2002). Establishment of the cell-to-cell transmissibility of some cytosolic self-aggregating proteins involved in distinct human disorders may allow soon their qualification as prions.

Overview

Despite being always viewed under the danger of their action and their heretical composition, prions are simply alternate structural states of proteins that, while perpetuating and transmitting, permit a fast and sustainable functional switch in response

to a trigger (Aguzzi and Calella 2009; Halfmann et al. 2010). In yeast, fungi, and mollusks, prions represent a beneficial biological tool for adaptation to environmental changes. For mammalian prions, the trigger remains unknown and is largely related to disease.

Proteins undergoing prion formation are structurally unrelated. However, according to the polypeptide chain, they can be classified into two groups. A first group is formed by those proteins containing a domain, generally featured by a high proportion of Q/N, which is indispensable for the function but hosts the prion formation capacity. The second group, exemplified by PrP, accounts for those chains in which the residues responsible for the prion function are scattered along the sequence.

Prion formation involves a conformational change in the precursor protein, which enables its polymerization. The resulting polymer is generally maintained by tightly packed intermolecular β -sheets that confer the assembly a peculiar resistance to degradation. Also, the feasibility of alternative packing arrangements makes possible a polymorphism in the assembly, which underlines the *strain* phenomena (Wiltzius et al. 2009).

Replication of prions occurs through the template-conversion of the precursor protein into its like. This reaction is a complex process involving steps of molecular recognition under the control of the protein sequence. Such recognition dependency sustains the *species-barrier* dependency of its transmissibility.

In addition to the previous traits, self-perpetuating protein aggregates become prions when they exhibit tractable cell-to-cell *transmission*. In prions from low organisms, transmission is linked to cell division and therefore follows an inheritable pattern, whereas in mammals, prions must travel from one cell to another (Aguzzi and Rajendran 2009).

Balearic Islands, Spain

Keywords

Archaea · Bacteria · Microorganism

Synonyms

[Bacteria](#)

Definition

Prokaryote (from Greek *pro* [before] and *karyon* [nucleus]) denotes organisms that lack a membrane-enclosed nucleus, as well as other [organelles](#).

Overview

Cellular life is represented by three lines of descent: the domains [Bacteria](#), [Archaea](#),

and [Eukarya](#). Two of them (*Bacteria* and *Archaea*) are embraced by the term “prokaryote,” a term that has no standing in the taxonomic hierarchy. From the phylogenetic reconstructions based on the analysis of the ribosomal small subunit gene sequences, it seems that both domains differ dramatically in their evolutionary history (see Fig. 1). In this regard, *Archaea* and *Eukarya* seem to share a common ancestor, whereas *Bacteria* seem to be an independent line of descent. In contrast to eukaryotic cells, prokaryotes have a simpler internal structure, lacking membrane-enclosed organelles. Prokaryotes do not develop or differentiate into multicellular forms. Some grow in filaments, or masses of cells, but each cell in the colony is identical and capable of independent existence, they never form specialized tissues. It is generally accepted that the first living cells on the earth were prokaryotes that might have appeared about 3.5 billion years ago or before, and remained alone for about 1.5 billion years until the eukaryotes developed (2.0 billion years ago). Prokaryotes are considered to be the most abundant living cells in the biosphere, with numbers that range from 4×10^{30} to 6×10^{30} , and that produce a biomass equivalent to that of the vegetal material. They colonize almost every place on the earth where life is possible, and

Prokaryote, Fig. 1 Phylogenetic reconstruction based on 16S rRNA gene sequence analyzes of the three domains of life. The figure shows that the Prokaryotes appear to be a paraphyletic group embracing Archaea and Bacteria

show the widest range of extreme life habitats. They colonize any available surface and cavity, and their abundance depends on the habitat. For example, 1 cm³ may contain about 10⁶ cells in seawater, 10⁹ in sediments, 10¹² in soils, 10¹⁰ in animal gut. Their metabolism is very diverse and can obtain energy from light (phototrophy), inorganic chemicals (chemolithotrophy), or organic chemicals (chemoorganotrophy). Some can fix inorganic carbon (autotrophy), but others depend on the assimilation of organic carbon (heterotrophy). Respiratory metabolism can occur aerobically (by reducing oxygen as a terminal electron acceptor), or anaerobically (by reducing a wide range of molecules such as sulfate, nitrate, iron, manganese, among others). On the other hand, some organisms ferment (reducing organic products of their own metabolism), or generate methane as a product of their anaerobic oxidative metabolism. In the prokaryotic world all these combinations are possible, and many of them can switch their metabolism depending on environmental conditions and the availability of different carbon and energy sources. The endosymbiosis of prokaryotes with eukaryotic cells had been essential for the development of the latter in the biosphere. Mitochondria seem to have originated from the symbiosis of an alphaproteobacterium, and gave eukaryotes the ability to respire oxygen. Chloroplasts seem to have their origin from a symbiosis with a cyanobacterium that gave algae and plants their photoautotrophic metabolism. Some animals show additional symbiosis with chemolithotrophs that provided them with an autotrophic metabolism. Prokaryotes are essential for the development of the biogeochemical cycles in the biosphere, and finally are responsible for recycling the basic elements that maintain life.

Archaea · Bacteria · Cenancestor · Early diversification of life domains · Last universal common ancestor

Definition

Prokaryotes are organisms constituted by cells lacking a nuclear membrane that separates the genetic material from the rest of the cytoplasm and, consequently, where transcription from

DNA to mRNA and translation from mRNA to proteins are coupled. As soon as mRNA begins to be synthesized, ribosomes begin to attach to it and translate it into protein on one end while transcription proceeds at the other end. There are two groups of organisms having a prokaryotic cell structure: ► [archaea](#) and ► [bacteria](#). The origin of prokaryotes refers to the origin and evolution of their shared common ancestor.

History

The terms *prokaryote* and *eukaryote* were introduced with their actual meaning in biology by microbiologists R. Stanier and C.B. van Niel in 1962. At that time, however, the third domain of ► [life](#), the archaea, had not yet been discovered, and prokaryotes were synonymous to bacteria. With the discovery of the archaea as a phylogenetically distinct domain of organisms, as distant from bacteria as from eukaryotes, it became clear that the term *prokaryote* should refer exclusively to a structural kind of cell but had no phylogenetic sense, since it grouped organisms from two far-distant groups.

Overview

The origin of prokaryotes can be viewed in two different ways, either as the origin of the ancestor from which archaea and bacteria diverged but also as the origin (specialization and/or diversification) of archaea and bacteria from that ancestor. The problem of the origin of prokaryotes is therefore intimately linked to that of the root of the tree of life and the evolution of the three phylogenetic domains of organisms. This is a highly debated and far-from-solved issue. Several theoretical possibilities have been proposed to explain the major splits in the three organismal domains, archaea, bacteria, and eukaryotes. One proposes that the last cenancestor (last universal common ancestor) was eukaryotic like and that prokaryotes derived from that ancestor by a reduction process, perhaps linked to the adaptation to high temperatures. This hypothesis is the least favored by

mainstream science, owing to the difficulties of explaining the origin of a rather complex eukaryotic cell early in evolutionary times from scratch. All the other hypotheses sustain the idea that prokaryotes emerged before eukaryotes and, hence, that the origin of prokaryotes is coincident with that of the last cenancestor. There are two major models for the evolution of the three domains of life from such a prokaryotic ancestor. The first proposes that the cenancestor splits in one branch leading to the bacteria and another branch that subdivided later into two branches corresponding to that of the archaea and to a third hypothetical protoeukaryotic branch in which the nucleus and several eukaryotic features such as phagocytosis evolved. This model, supported by C.R. Woese, is the most popular and the one explained in most textbooks. A related, though quite minority, model proposing the existence of a protoeukaryotic lineage sister to the archaea is that by T. Cavalier-Smith, who proposes that archaea and eukaryotes derive from within Gram-positive bacteria, sharing with them the possession of only one cell membrane. The second, increasingly expanding, set of models proposes that the last cenancestor simply split into two major branches leading to, respectively, archaea and bacteria. Eukaryotes would be the evolutionary outcome of one (or two) symbiotic event(s) between archaea and bacteria. The bifurcation between the archaeal and bacterial lineages would have been accompanied by a specialization of their membrane lipids and the replication machinery of DNA, which are very different in both lineages, as well as the fine-tuning of transcription and translation. The last cenancestor from which archaea and bacteria evolved was certainly a rather complex organism, but how and when it evolved from earlier life forms remain obscure at present.

Proper Motion

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Synonyms

[Apparent motion](#)

Definition

The proper motion is the apparent angular motion of a star or any celestial object on the

celestial sphere, as measured from the position of the Sun. Proper motion is given in arc seconds per year for each component of the equatorial coordinates (► [right ascension](#) and ► [declination](#)). Proper motion should not be confused with ► [parallax](#), which is the apparent motion of a star on the sky in 1 year, caused by the motion of the Earth as it travels along its orbit around the Sun.

Since the apparent motion is due to the star's velocity with respect to the Sun, the proper motion is proportional to the ratio of transverse velocity to distance; it is consequently larger when the star is nearby (Fig. 1). For instance, Barnard's star, one of the closest stars to the solar system (6 light-years), has the largest proper motion of all stars, moving at 10.3 s of arc per year (Fig. 2).

Until recently, proper motions of stars were obtained by comparing photographic sky survey images taken many years apart. The European ► [Hipparcos](#) satellite brought a revolution in the 1990s by providing much more accurate proper motion measurements for several millions of stars. The Gaia space mission launched in fall 2013 will extend the catalog to a billion stars with another very big step in accuracy.

Proper Motion, Fig. 1 A star has a certain velocity through space with respect to the Sun, and the transverse component of this velocity corresponds to the proper motion

Proper Motion,

Fig. 2 The nearby Barnard's star exhibits a very large proper motion, as illustrated by the measurements obtained by the European satellite Hipparcos

Since stars with large proper motions tend to be nearby, this is a way to select targets for exoplanet searches, either for direct detection or when the astrometric technique is used.

Definition

The molecule propyl cyanide has two isomers, both of which have been detected in interstellar molecular clouds. The straight-chain isomer, *n*-propyl cyanide, is also called 1-cyanopropane, butyronitrile, or butanenitrile (the IUPAC name); while the branched form, *i*-propyl cyanide, is also known as 2-cyanopropane, *iso*-butyronitrile, and 2-methylpropanenitrile (IUPAC name). Moreover, *n*-propyl cyanide has two conformers, *anti*- or *a-n*-propyl cyanide and *gauche*- or *g-n*-propyl cyanide, where the former has a planar heavy atom frame and the latter has the CH₃-group or the CN-group rotated by 120°.

History

Propyl cyanide is among the largest organic molecules unambiguously detected by radio astronomers in the ▶ [interstellar medium](#). The lower energy, *anti*-conformer of *n*-propyl cyanide, was detected in the Galactic Center molecular cloud Sgr B2(N) by Belloche et al. (2009), who suggested that it may be produced by surface reactions on ▶ [interstellar dust](#) grains, perhaps by sequential addition of CH₂ or CH₃ radicals to known interstellar species such as CN and CH₂CN. It is the third member of the series that includes methyl cyanide (CH₃CN) and ▶ [ethyl cyanide](#) (CH₃CH₂CN).

Both the *gauche*-conformer of *n*-propyl cyanide and the isomer *i*-propyl cyanide were

subsequently detected in the same source by Belloche et al. (2014) using ALMA, and more recent observations have detected both isomers in the Orion molecular cloud. *I*-propyl cyanide is the first detected interstellar molecule that has a branched carbon backbone.

CH₃CHCH₂O

Definition

Propylene oxide (CH_3CHCH_2O) is a cyclic, chiral organic molecule detected in the interstellar medium toward the Sagittarius B2(N) high-mass star-forming region.

Structure

History

An unsuccessful attempt to detect propylene oxide in Sgr B2 and Orion was reported by Cunningham et al. (2007) using mm-wavelength observations. The successful detection of propylene oxide was later reported by McGuire et al. (2016) in the PRIMOS Molecular Line Survey of Sgr B2(N) using the Green Bank Telescope, and in confirming observations with the Parkes Radio Telescope, all at cm-wavelengths. It is the first chiral molecule to be detected outside the Solar System. The measurement was not able to discern whether an enantiomeric excess was present in the source. Theoretical work by Salzman (1998) has suggested that propylene oxide may be an excellent candidate molecule for observing microwave circular dichroism for the first time, providing a possible means by which an excess could be observed.

Chemical Formula

C_3H

Definition

The radical C_3H can exist in either a linear form ($l-C_3H$) or as a tricarbon ring with the attached hydrogen atom ($c-C_3H$). Both isomers have been detected at millimeter wavelengths in the interstellar medium and in the envelopes of evolved

stars. C_3H is an important intermediary in the production of heavier species of the form C_nH ($n > 3$), which have been detected astronomically for $n = 4$ –8. The linear propynylidynium ion, C_3H^+ , has also been reported in the interstellar medium (Pety et al. 2012).

William M. Irvine
Department of Astronomy, University of
Massachusetts, Amherst, MA, USA

Synonyms

[Propynylidynium](#), $\text{l-C}_3\text{H}^+$

Definition

The cation C_3H^+ is thought to play an important role in gas phase reactions in the ► [interstellar medium](#) that lead to the formation of small

hydrocarbons. The neutral radical, C_3H (► [propynylidyne](#)) can exist in both a linear ($\text{l-C}_3\text{H}$) and a cyclic ($\text{c-C}_3\text{H}$) form, and both these neutral species have been detected in interstellar molecular clouds.

History

A detection of the linear cation C_3H^+ (denoted $\text{l-C}_3\text{H}^+$) in an interstellar ► [photodissociation region](#) was first reported by radio astronomers (Pety et al. 2012). Although in the absence of laboratory data on its rotational spectrum the identification was initially questioned, the carrier of the detected emission lines was subsequently detected in other molecular clouds (McGuire et al. 2013). Laboratory spectra and very accurate theoretical calculations have Brünken et al. (2014) and Botschwina et al. (2014) confirmed C_3H^+ as the carrier of the lines observed by radio astronomers. Recent observations confirm that this ion is ubiquitous in the diffuse interstellar medium (Gerin et al. 2019).

Definition

A protein is a biopolymer comprised of a linear chain of amino acids. Proteins not only act as the main catalytic molecules of life in the form of enzymes, they also serve structural, mechanical, and signaling roles, as well as other cellular functions. The chemical properties of amino acids and their sequential organization determine how a protein folds into a three-dimensional structure. This structure, in turn, dictates the function of the protein molecule. Instructions for the amino acid sequence of a protein are stored in the genetic material of a cell in the form of a gene.

History

According to the “RNA World” hypothesis, prior to the evolution of protein synthesis, RNA oligonucleotides acted as both the information carrier and the catalytic molecule of life. If true, proteins eventually replaced these oligonucleotides as superior catalytic molecules. Today, proteins are largely responsible for a cell’s metabolism and play a key role in most cellular processes. Although proteins are most noted for their catalytic capabilities, they also act as key structural components of cells, having important roles in the cytoskeleton and transport of small molecules through the cellular membrane. Researchers are able to study ancient life through a process termed ancestral sequence reconstruction to gain insight into ancient proteins, ancient organisms, and the environments in which ancient organisms may have lived. Across the domains of life, all proteins are made up of a canonical set of 20 different amino acids. However, evidence suggests that early proteins were likely synthesized from a reduced set of amino acids and that this set evolved over time to incorporate additional amino acids which have expanded chemical functionalities. Some interesting questions astrobiologists attempt to address include why nature selected these particular 20 amino acids, what was the function of early proteins, and how did the protein synthesis machinery evolve.

Overview

Proteins are linear biopolymers composed of a non-branching chain of amino acid monomers. All amino acids consist of a hydrogen atom, an amino group, a carboxyl group, and an R-group attached to a central alpha carbon. The R-group varies among amino acids and is the distinguishing feature between one amino acid and another. The various R-groups allow amino acids to exhibit a range of solubilities, hydrophobicities, and reactivities while maintaining a basic structure. Although dozens of different amino acid species can be observed in meteorites or as products in prebiotic synthesis experiments, all

Protein, Fig. 1 L and D amino acids. Biotically synthesized amino acids are found in the L configuration. However, abiotic amino acids, including those synthesized in labs or identified in meteors, can exhibit either chirality

known life uses the same set of 20 (or, in some cases, 22) amino acids for protein synthesis. This conservation of proteinogenic amino acid species, along with their uniform chirality (L) and central alpha carbon, led to one of the first hypotheses that all life on Earth evolved from a common ancestor (Fig. 1).

The sequence of amino acids comprising a protein is specified by its corresponding gene in the cell's genetic material and determines the structure and function of the protein. The sequence of amino acids is known as the primary structure of a protein. As a protein is synthesized (i.e., translated), the various chemical properties of the amino acid R-groups (such as size, charge and polarity) lead to chemical interactions that cause the growing chain of amino acids to adopt a three-dimensional structure. Local regions of a protein generally form alpha-helix or beta-sheet conformations, which can then fold to bring distal regions of the protein into close proximity. Alpha-helices and beta-sheets are classified as types of secondary structure. The three-dimensional arrangements of alpha-helices and beta-sheets in relation to each other create the protein's tertiary structure. Some proteins also have quaternary structure when multiple three-dimensional proteins associate as subunits to form a larger protein complex (Fig. 2). Chemical modifications of proteins (post-translational modifications) are often used to stabilize or modify protein structures (i.e., disulfide bonds) or to change their chemical and functional properties (i.e., methylation).

To assemble a protein's primary structure, individual amino acids are linked by a peptide bond between the carboxyl group of one amino acid and the amino group of the next amino acid via a condensation reaction. Due to resonance

structures, the peptide bond has some double-bond characteristics that make it much more rigid and slightly shorter than a true single-bond. Additionally, the six atoms comprising the peptide group are planar in spatial organization, which imparts rigidity to the peptide backbone (Fig. 3). These restrictions severely limit the number of conformations a protein's backbone can adopt. Such rigidity provides the peptide chain with a constrained shape and limited flexibility, and, thus, explains the prevalence of the secondary structural elements discussed above.

The alpha-helix and beta-sheet conformations allow hydrogen bonding between the positively charged amino groups and the negatively charged carboxylate groups along the backbone of a protein. Since the amino and carboxyl groups are charged at physiological pH, the result of these associations is the hydrophobicity of the protein is controlled by the amino acid R-groups, the side chains which differ among amino acids and lend them specific functionality, as opposed to the protein backbone, which is common to all proteins. Thus, not only can proteins demonstrate a wide range of hydrophobicities, but even within a single protein, different regions can have different hydrophobicities. A random coil (also called a beta-turn or a reverse turn) is another class of secondary structure identified by the absence of a regular secondary structure. These are amino acid sequences which are not part of an alpha-helix or beta-sheet but often connect these more common secondary structures.

The design of the secondary structure participates in the formation of the tertiary and quaternary structure of the protein. Proteins must balance hydrophobic and hydrophilic properties in order to fold properly and fulfill their prescribed cellular function. For example, proteins active in the cytoplasm must be water-soluble. Additionally, the exterior of the protein and the interior of the protein may have different hydrophobicities. For example, a transport protein in a cell's membrane would have a hydrophobic exterior so it can span the lipid bilayer, while the interior core of the protein might be hydrophilic to allow water-soluble molecules passage between the interior and exterior of a cell, a passage not otherwise possible with a lipid bilayer.

Protein, Fig. 2 Ancient uricase structure. Above are cartoon depictions of the crystal structure of an ancient uricase. Frame (a) shows the primary structure of a beta-strand, part of a beta-sheet, whose sequence is histidine, valine, isoleucine, arginine, alanine, glutamine, valine, tyrosine, and valine *left to right*. Carbon atoms are *green*, nitrogen are *blue*, oxygen are *red*, hydrogen are *white*. The peptide backbone bisects the frame with the amino acids' R-groups protruding above and below the backbone. Frame (b) depicts alpha-helix (*blue*) and beta-sheet

(*magenta*) structures with the remaining portions colored salmon. Frame (c) illustrates the protein's tertiary structure. The *magenta* beta-sheets and *blue* alpha-helices make up the peptide strand's three-dimensional structure. In Frame (d), four monomers associate as a tetramer forming the proteins' quaternary structure. One monomer is highlighted in *magenta*; the other three are *green*. To make a functional uricase enzyme, 11 of these tetramers would associate to make the full protein complex

P

Protein, Fig. 3 Planar peptide group. The six planar atoms surrounding the peptide bond, highlighted by the *blue* polygon, impart rigidity to the peptide's primary structure, leading to the formation of the most common secondary structures, alpha-helices and beta-sheets

Proteinoid Microsphere

Koichiro Matsuno
Nagaoka University of Technology, Nagaoka,
Japan

Keywords

Amino acids · Microspherules · Protocells

Synonyms

[Thermal copolymers of amino acids](#)

Definition

Proteinoid microspheres are spherical structures to be formed when a heated mixture of amino acid molecules in the dry conditions is dissolved in water. The diameter of a typical microsphere is about a few micrometers.

Overview

The first experimental observation of proteinoid microsphere was made by Sidney W. Fox, Kaoru Harada and their colleague in 1959 (Fox et al. 1959). The term proteinoid coined by Fox is for a thermal copolymer of amino acid molecules. Proteinoids maintain within themselves side-chain bonds in addition to peptide bonds.

Proteinoids readily form microspherules in water. This is due to the fact that they are amphiphilic, consisting of molecules having a polar water-soluble group attached to a water-insoluble group. The presence of a polar water-soluble group which can easily be ionized has indirectly been confirmed in a dynamic manner by observing the oscillation of electrical potential of the surface of proteinoid microspheres. In addition, when the proteinoids are rich in basic amino acids such as arginine and lysine, the surface of the resulting microsphere can have local areas where naked positive charges are exposed directly to the immediate surroundings. These naked positive charges can attract some types of molecule having negatively charged locales. A typical example of molecule having negatively charged locales includes both amino acids and nucleic acids. The surface of proteinoid microspheres may provide a reaction site for further chemical synthesis to follow. Furthermore, proteinoid microspheres can exhibit some forms of dynamic structural flexibility including an instance of giving birth to daughter microspheres through budding when the ionic strength or the pH of the aqueous milieu is changed.

Then, it would seem to follow that proteinoid microspheres may serve as a model of proto-cell in prebiotic evolution as championed by Fox. However, the subtle part in the claim of proteinoid microspheres as a model of protocell is in the difficulty of refuting the claim itself. A reliable model must be explicit in drawing the demarcation line beyond which it is not applicable. Although the model of proteinoid microspheres does not meet the requirement yet, this does not mean that it is irrelevant. The future fate of the proteinoid model remains to be seen.

Definition

Many proteins are composed of more than one folded polypeptide chain, which are known as ► [protein](#) subunits. Quaternary structure describes the organization of multiple subunits into a complex. Some examples of proteins with quaternary structure include hemoglobin and many ion channel proteins. Changes in quaternary structure can occur through conformational changes within individual subunits or through reorientation of the subunits relative to each other. These conformational changes, which may be cooperative or allosterically (induced by binding of other molecule) effected, often govern the mechanism by which proteins are regulated or perform their catalytic functions.

Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

In biochemistry, ► [protein](#) secondary structure describes common three-dimensional structural motifs found in proteins. Secondary structure is determined by inter-residue interactions mediated most often by hydrogen bonding occurring between backbone amide nitrogen and carbonyl groups of a polypeptide. The most common secondary structural motifs are ► [alpha helices](#) and beta sheets. Tight turns and flexible loops link the regular secondary structural elements.

Amino acids in a polypeptide vary in their tendency to form secondary structure elements. Proline and glycine are sometimes called “helix breakers” because they tend to disrupt the regularity of α -helical backbone conformations; however, both of these amino acids have unusual conformational abilities and are often found in turns. Amino acids that prefer to adopt helical conformations in proteins include methionine, alanine, leucine, glutamic acid, and lysine. In contrast, large aromatic amino acids such as tryptophan, tyrosine, and phenylalanine, and branched amino acids such as isoleucine, valine,

and threonine generally prefer to adopt β -strand conformations.

Definition

In biochemistry, the tertiary structure of a ► [protein](#) is its three-dimensional structure, as defined by the atomic coordinates. Tertiary structure is largely determined by the protein’s primary and secondary structure. The environment in which a protein is synthesized and allowed to fold is a significant determinant of a polypeptide final folded conformation. In globular proteins, tertiary structure is often stabilized by the sequestration of hydrophobic amino acid residues in the protein’s interior, from which water is excluded, and by the exposure of charged or hydrophilic residues on the protein’s cytosol-exposed surface.

Proteobacteria

Irma Marín

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Ciudad
Universitaria de Cantoblanco, Madrid, Spain

Keywords

Alphaproteobacteria · Betaproteobacteria ·
Deltaproteobacteria · Epsilonproteobacteria ·
Gammaproteobacteria

Definition

Proteobacteria is the largest and most diverse phylum of the domain Bacteria.

Overview

Proteobacteria is an evolutionarily, geologically, and environmentally important group of microorganisms. All proteobacteria are ► [Gram-negative bacteria](#), with an outer membrane mainly composed of lipopolysaccharides. Members of this phylum show extreme ► [metabolic diversity](#), including chemoautotrophic, chemoorganotrophic, and phototrophic microorganisms, which represent most of the known bacteria of medical, industrial, and agricultural significance. Photosynthetic proteobacteria are called purple bacteria, referring to their reddish pigmentation. Most members of the phylum are facultative or obligate anaerobes, with gas vesicles, flagella, or the ability to move by gliding. Morphologically, they show a variety of cellular forms including rods, curved rods, ovoids, and spirals, and some have stalks or other appendages. There is evidence that eukaryotic mitochondria originated from an endosymbiotic relationship with a member

of this group of bacteria. Phylogenetically, the group is defined on the basis of sequence of the small ribosomal subunit RNA gene (16S rRNA) and is divided into five classes: *Alphaproteobacteria*, *Betaproteobacteria*, *Gammaproteobacteria*, *Deltaproteobacteria*, and *Epsilonproteobacteria*.

The *Alphaproteobacteria* comprise numerous phototrophs, chemolithotrophs, and chemoorganotrophs. Some members of this group are symbionts of plants and animals, and others have adopted intracellular life styles and constitute important human and animal pathogens.

Betaproteobacteria consist of several groups of aerobic or facultative bacteria, which are often highly versatile in their degradation capacities. Many of the species of this class play a role in ► [nitrogen fixation](#) in various types of plants or are able to use ammonium, hydrogen, or methane as a source of energy.

Gammaproteobacteria are the largest subgroup of proteobacteria. Many pathogens belong to this class. Many genera are chemoorganotrophs and facultative anaerobes, while others are chemolithotrophs. Some members of this group are photosynthetic using hydrogen sulfide as environmental reducing power.

Deltaproteobacteria is comprised of chemoorganotrophic microorganisms. This class can be divided into two branches. Aerobic predators and fruiting-body-forming bacteria have been found among one, while most of the known sulfate- and sulfur-reducing bacteria, an activity associated to the sulfur cycle, belong to the other.

Epsilonproteobacteria consist of few known genera with symbionts or pathogens species for humans or animals. Some environmental sequences have been recovered from cold and hydrothermal environments.

Proteome, Proteomics

Carlos Briones

Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Definition

A proteome is the complete set of ► [proteins](#) encoded by a ► [genome](#). It is also defined as the ► [protein](#) complement of the genome. Whereas the proteome of a species is the whole set of potentially expressed proteins, the proteome of

an individual organism displays variations according to the cell cycle, metabolic status, and environment-dependent variables. In multicellular organisms, the proteome is the subset of all encoded proteins which is expressed in a cell or tissue, also affected by the developmental stage and health of the organism. Proteomics is the field of molecular biology which studies the entire proteome for determining the structures and functions of the expressed proteins, as well as the relationships among them. Technologies widely used in proteomics include two-dimensional gel electrophoresis, mass spectrometry, techniques for structural characterization of proteins, and proteome-focused bioinformatic tools. In parallel to proteomics, other global and high-throughput “omic” fields have been developed including transcriptomics, interactomics, and metabolomics, where each of these fields involves the study of the entire set of transcribed mRNAs, protein-protein interaction networks, and metabolites within the cell, respectively. The basic and technological advances in the current “post-genomic era” have profound consequences in biology, medicine, and environmental sciences.

Proterozoic Eon

Felix M. Gradstein

University of Oslo, Blindern, Norway

Keywords

Banded iron formation · Eukaryotes · Geological timescale · Great oxygenation event · Precambrian

Definition

The Precambrian includes the informal Hadean eon, as well as the formal Archean and Proterozoic eons. The latter is the youngest, which ranges from 2,500 to 538.8 Ma.

Overview

The Proterozoic Eon begins at 2.5 Ga, which approximately marks the time when oxygen from cyanobacteria began to dramatically change the composition of the Earth's atmosphere and oceans and when complex one-celled life (eukaryotes) evolved from simple cells (prokaryotes). The Proterozoic is subdivided into ten periods, generally of 200-Myr duration, grouped into three eras. The poetic names for these periods (see International Stratigraphic Chart: www.stratigraphy.org) are derived from the larger-scale tectonic or sedimentary features that occurred within each period. For example, the Siderian Period (2.5–2.3 Ga) is named from the banded iron deposits (σίδηρος = sideros = iron) that peaked within that interval. The lack of a diverse and well-preserved fossil record, the sparse volume of supracrustal rocks, a variable degree of metamorphism and tectonic disturbance, and the uncertainties in the configuration of the continents all contribute to making the establishment of a chronostratigraphic timescale beyond the Phanerozoic Eon problematical. Therefore, the main method for correlation of Precambrian strata requires radiometric ages of interbedded volcanic rocks. The Precambrian Subcommittee of the International Commission on Stratigraphy (www.stratigraphy.org; see also Gradstein et al. 2020) is striving to establish a more “natural” set of subdivisions that incorporates major tectonic, biologic, atmospheric, and geochemical events.

Protists

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

Protists are a diverse group of eukaryotic microorganisms that encompass mostly unicellular and some ► [multicellular organisms](#) that do not fit phylogenetically into the well-defined kingdoms: Animalia, Plantae, and Fungi. Historically, protists were treated as the kingdom Protista, but this group has been contested in modern taxonomy. Protists do not have much in common besides a relatively simple organization, either unicellular or multicellular, with no specialized tissues. The term protista was first used by Ernst Haeckel in 1866. Protists live in almost any environment that contains liquid water. Most protists, such as ► [algae](#), are photosynthetic and are fundamental primary producers in many ecosystems, making up a large part of the plankton of the oceans.

Binary star · young · Protostar

Definition

Binaries are pairs of stars locked into orbit around each other by their mutual gravitational attraction. When both stars are too young to undergo hydrogen fusion, the system is called a protobinary. In the very youngest protobinaries, neither star is optically visible, since both are still heavily embedded in the dust and gas that formed them. Several hundred protobinaries are known. In a few cases, the actual orbits of the component stars have been partially traced. Most protobinaries, however, are detected as close pairs of stars that share a common space motion within a young stellar cluster.

Overview

Most stars are not isolated objects, but have an orbiting companion. This fundamental fact was first established in the 1960s through surveys of main-sequence G-type stars, i.e., objects similar to the Sun. Over the last two decades, it has emerged

that pairing is also common among much younger stars. The term protobinary refers to a pair of stars in which the components are either ► [protostar](#) or ► [pre-main-sequence star](#). In the former case, each star is still accreting gas from its parent molecular cloud. A pre-main-sequence star, on the other hand, has reached its final mass, but is still too young to undergo hydrogen fusion at its center.

Both protostars and the youngest pre-main-sequence stars are still heavily obscured by surrounding dusty gas. Protobinaries are therefore only seen at infrared and longer wavelengths. The actual radiation detected comes from dust grains that are being heated by the stars within. Thus, the emitted spectrum depends more sensitively on properties of the dust than on properties of the star itself. It is therefore not surprising that the true evolutionary state of the many known protobinaries is uncertain.

In principle, one could identify a protobinary by seeing each star trace an orbit around the other. In practice, the spatial resolution at longer wavelengths makes such observations difficult, although they have been achieved using interferometers. Most of the known protobinaries were found, instead, as close pairs of infrared or millimeter point sources that share a common space motion within a young stellar cluster. Here, the physical separations range from several 100 to 1,000 AU. Assuming both stars to be of roughly solar mass, the corresponding periods are 1,000–30,000 years.

In some cases, optically visible, pre-main-sequence stars are accompanied by others that are still deeply embedded. The nature of these infrared companions is still unknown. It is doubtful that they are truly younger than the visible star for the following reason. When *both* stars in a binary are optically visible, pre-main-sequence stars, it is possible to measure their ages individually. These ages, typically a few million years, usually match fairly well. This finding also indicates that the components of protobinaries were born together, presumably out of a common molecular cloud core.

Compartmented reaction systems · Lipid self-assembly · Prebiotic membranes · Protometabolism · Vesicles

Synonyms

[Artificial cells](#); [Cell models](#); [Synthetic cells](#)

Definition

A protocell is any experimental or theoretical model that involves a self-assembled compartment (typically a supramolecular structure, like a

lipid vesicle) linked to chemical processes taking place around or within it, aimed at explaining how more complex biological cells or alternative forms of cellular organization may come about.

Overview

Terrestrial biology is based on cells – systems that produce their own boundaries and carry out various transformation and replication processes within those boundaries. This includes processes leading to cell growth, cell division, and evolution of interacting cell populations. Furthermore, there are several good reasons to believe that the generation of any living entity, terrestrial or not, requires cellular compartmentalization (Morowitz 1992; Harold 1986). However, the level of molecular and organizational complexity shown by even the simplest known ► [prokaryotes](#) is so high that their origin remains a mystery. Different ideas to tackle this problem scientifically have been proposed. In some of them, compartmentalization through membranes is considered a late (or even the last) major event in the process, under the assumption that all the necessary prebiotic chemistry leading to biopolymer chemistry could have taken place in bulk (aqueous) solution, perhaps with the help of mineral surfaces. For approaches that, instead, consider that membrane compartments or colloidal organic interfaces must play an important role at an earlier prebiological stage, the idea of “protocell” becomes central. A protocell would be any chemically reacting system organized around or within a self-assembled, supramolecular boundary, which mimics – without fully reproducing – the behavior of biological cells. This is an important concept not only for the traditional research program in the origins of life, but also for related emerging fields of synthetic biology, artificial life, and astrobiology.

Early ideas on protocellularity involved quite diverse systems (Hanczyc 2009), which did not always resemble modern cells topologically nor in the molecular composition and structure of the boundary (e.g., Oparin’s “coacervates” or Fox’s “proteinoid microspheres”). Nevertheless, the

development of liposome technologies in the last few decades has made it possible to elaborate and implement model systems in the laboratory using lipid or amphiphilic bilayers, which contain – and are contained in – aqueous solutions, sharing many properties with biological membranes. Depending on the types of compounds making up the protocells (i.e., their boundary and their internal micro-environment), different models have been put forward over the years. For instance, due to their higher prebiotic plausibility, fatty acid vesicles have recently attracted attention of many researchers in the area, even if they are less stable and much more permeable, in general, than phospholipid membranes (Morigaki and Walde 2007; Deamer 2008). Regarding internal components and their dynamics, there is presently great interest in coupling vesicle growth and reproduction with polynucleotide replication taking place within the compartment (e.g., Mansy et al. 2008). Although the chemical logic of a minimum protocell would not necessarily involve complex macromolecules, like nucleic acid chains or other biopolymers (Morowitz et al. 1988), it seems that the search is currently focused on finding a protocell that can evolve – or be evolved – in a “Darwinian” way (i.e., with a mechanism for reliable heredity of molecular sequences), perhaps expecting that other relevant features of the system (robustness, internal lipid production, autonomous energetic viability, membrane functionalization, etc.) will derive from there. In the next years, it will become clearer whether this type of experimental shortcut proves successful, whether some other semisynthetic alternative (Luisi et al. 2006; Chen and Walde 2010) provides more solid results, or whether the bottom-up construction of functional protocells actually requires a longer, more winding pathway.

Proton Irradiation

Kensei Kobayashi

Yokohama National University, Yokohama, Japan

Definition

Irradiation of a medium by high-energy protons (hydrogen ions) by using accelerators such as Van de Graaff accelerators and synchrotrons is called

proton irradiation. Cosmic rays are one of the possible energy sources for ► [prebiotic chemistry](#), and protons are predominant in cosmic rays. Thus, a number of proton irradiation experiments have been performed. The energy of the protons used in these experiments is usually a few MeV (mega electron volt; 10^6 eV) or higher. Not only the high-energy protons but also secondary electrons (electrons formed by the interaction of initial protons and target molecules) are effective for dissociation and ionization of molecules. Proton irradiation causes less specific chemical reactions than UV irradiation.

Proton irradiation of gas mixtures containing carbon species like methane or carbon monoxide and nitrogen species like nitrogen and ammonia produces a wide variety of organic compounds including precursors to amino acids (Koyabashi et al. 1998) and nucleic acid bases. In addition to irradiation of gas mixtures, proton irradiation of ice mixtures simulating ice mantles of ► [interstellar dust](#) particles has often been performed, to examine the possible role of cosmic rays in interstellar space (particularly in ► [molecular clouds](#)) (Kasamatsu et al. 1997). In these experiments, major targets have included carbon monoxide, methane, methanol, ammonia, and water ices. ► [Amino acids](#) were also detected after hydrolysis of the resulting irradiation products.

Proton irradiation is also used to determine the tolerance of organisms to cosmic radiation.

ATPase · ATP synthase · Electrochemical potential · LUCA · Proton gradient · Proton pump · Sodium motive force

Synonyms

[Chemiosmotic potential](#); [Electrochemical potential](#)

Definition

Proton motive force (PMF) is the force that promotes the movement of protons across membranes downhill the *electrochemical potential*.

Overview

A difference of solute concentration between two compartments separated by a biological *membrane* generates a tendency to equilibrium, which, in the case of protons, is called proton motive force (PMF). This is measured in terms of the potential energy resulting from the difference in concentration between the two compartments. With a charged solute, the potential has two components: the chemical (concentration) and the electrical potentials (Fig. 1); thus, it is named *electrochemical potential*; thus proton motive force can be calculated as $\Delta p = \Delta \Psi - (2.3RT/F)(pH_{in} - pH_{out}) = \Delta \Psi - (2.3RT/F)\Delta pH$ ($\Delta \Psi$ is the transmembrane difference of electrical potential) (Harris 1995).

This energy can be used in different ways such as performing chemical work, particularly in the synthesis of *ATP* by *ATP synthases*, osmotic

Proton Motive Force, Fig. 1 Proton gradients and proton motive force

Proton gradients require energy to be formed ($G > 0$) and generate the proton-motive force, which favours re-establishing the equilibrium ($G < 0$)

Certain membrane-associated proteins can use energy to generate proton gradients (E) and/or use the generated proton-motive force to make different types of work (W)

Heat production	Decoupling of oxidative phosphorylation
Osmotic work	Ions or molecules transport coupled to proton translocation
Chemical work	Reactions of : H^+ -ATP-synthase H^+ -Pyrophosphate synthase H^+ -Transhydrogenase Reverse electron transport
Mechanical work	Prokaryotic flagellar movement Gliding movement of filamentous cyanobacteria

Proton Motive Force, Fig. 2 Proton motive force (PMF) can be used to perform different types of work

work, promoting different types of secondary transport, mechanical work, for example fueling flagellar or gliding movement of some bacteria, and, in some cases, generating heat (Fig. 2).

Proton gradients can originate in different ways and are an energy source for cells. In animal and plant cells, proton gradients are generated in mitochondria by means of the vectorial transport of protons driven by components of the respiratory chain. In plants, photosynthetic electronic transport also generates proton gradients in *chloroplasts* in which regulation of the two components of the PMF is essential for a correct response of photosynthetic light reactions to changing

environmental conditions (Armbruster et al. 2017; Li et al. 2021). In animal mitochondria PMF is not only used to synthesize ATP but for regulating proteostasis and linked to mitophagy and aging (Berry and Kaerberlein 2021). In some studies a relationship between PMF and certain characteristics of cancer cells has also been proposed (Brown and Ganapathy 2020).

In most *bacteria* and *archaea*, the electronic transport chain generates proton, and/or Na^+ , gradients, but fermenting bacteria use membrane-linked *ATPases* to hydrolyze ATP for uphill transport of protons. *Halobacteria*, a group of *Archaea* living at high salt concentrations, use

bacteriorhodopsin, a light-driven membrane protein to generate a proton gradient.

The wide use of PMF in several biological processes makes it a target for substances that may affect various processes. In bacteria PMF has been related to resistance (Crabbé et al. 2019; Feng et al. 2015; Le et al. 2021; Wu et al. 2019) or tolerance (Liu et al. 2018) to certain antibiotics, the capability to form *biofilms* (Ikonomidis et al. 2008), the natural competence involved in horizontal gene transfer (Domenech et al. 2020), and also may affect virulence of some bacteria (Iqbal et al. 2021).

Most extant organisms use PMF; however, the use of proton gradients might not have been the first gradient used by life systems. Some researchers suggest that this may be a mechanism that evolved from a more ancestral one based on Na^+ gradients, used by organisms when membranes were quite proton leaky (Dibrova et al. 2015; Mulikidjanian et al. 2008). The persistence of the use of a sodium motive force (SMF) by some obligate *anaerobes*, *thermophiles*, and *alkaliphiles* may be due to their low energy budgets that do not allow them to cope with the energy losses due to the proton leakiness of the modern membranes (10^5 – 10^7 times that of Na^+ ions). However, some authors claim that the last universal common ancestor (*LUCA*) used natural proton gradients (Lane 2017; Lane et al. 2010; Milshteyn et al. 2019). The evolutive origin of the use of ion gradients for *bioenergetics* purposes is still a very controversial issue. Extremophile organisms use different approaches for coping with environmental conditions that might affect the PMF (Baker-Austin and Dopson 2007; Matin 2009; Matsuno et al. 2018).

[Circumstellar disk](#); [Planet-forming disk](#); [Proplyd](#)

Definition

A protoplanetary disk is a flattened, rotating structure surrounding a young star, out of which planets form. They are composed of gas and dust, with temperatures ranging from over a thousand Kelvin close to the star to a few tens of Kelvin further away, and they emit from infrared to millimeter wavelengths. The largest disks have radii of several hundred astronomical units ($\sim 10^{13}$ m) and masses a few tenths of a solar mass ($\sim 10^{29}$ kg), though most are considerably smaller and less massive. Disks have diverse evolutionary pathways and lifetimes that range from less than 1 to greater than 10 Myr.

History

The concept of protoplanetary disks dates back to the eighteenth century, inspired by the motions of the planets in the solar system. Astronomers realized that the planets move in the same direction around the Sun, in approximately the same plane and in almost circular orbits. This led to the nebular hypothesis, initially outlined by Descartes and Swedenborg and developed by Kant in 1755 and Laplace in 1796, that the planets originated from a rotating disk of material that, at some point in the past, encircled the Sun. Modern science has revealed a compositional continuum and strikingly similar ages between the Sun, Earth, and meteorites, now extended to other planets, asteroids, and comets that demonstrate beyond refute a common origin for the solar system in a disk around the young Sun. Analogous disks around nearby young stars were indirectly inferred in the 1980s and then directly imaged in the 1990s. Most recently, newly formed planets have been detected in disks and ever more detailed observations test increasingly sophisticated theories.

Overview

Protoplanetary disks are a natural outcome of the ► [star formation](#) process by which a ► [molecular cloud](#) core collapses under its own gravity.

Conservation of angular momentum over this tremendous compression of size scales, from approximately light year to solar radii (10^{16} to 10^9 m), results in a rapidly spinning disk, flattened perpendicular to the rotational axis. The disk forms quickly while the ► [protostar](#) is enshrouded by the ► [dense core](#) and optically invisible. As the protostar grows, the core loses mass and is dispersed by radiation, winds, and outflows through stellar feedback. Within a few 10^5 year, the star becomes optically visible and, having reached its final mass, slowly contracts as gravitational potential energy is radiated away. Historically, the term protoplanetary disk referred only to the disks found around optically visible ► [pre-main sequence stars](#) (also known as ► [T Tauri stars](#)), but it is now recognized that the first steps of planet formation begin in the earlier, embedded phase of protostellar growth, and we use a more general definition here in considering any disk that has the potential to form planets independently of the precise stage of star formation.

Disks inherit their composition from the ► [interstellar medium](#) with a mass ratio of 74% molecular hydrogen, 25% helium, and only 1% heavier elements that reside predominantly in sub-micron-sized ► [dust grains](#). However, they vary widely in almost every other aspect, in particular size, with radii varying from ~ 1 to 100 au ($\sim 10^{11-13}$ m) and mass ranging from less than one to over one hundred times that of Jupiter ($\sim 10^{27-29}$ kg). This inherent diversity is likely due to the turbulent conditions in the collapsing core. Due to internal friction, or ► [viscosity](#), a rotating disk will spread out with time. The inner disk accretes onto the star, and gas in the outer disk is lost through photo-evaporation. The dust grains stick together and grow to millimeters and beyond, such that the solids decouple from the gas, settling to the midplane and concentrating in regions of high pressure. The accumulation of solids is the first step toward the formation of ► [planetesimals](#). Water and other compounds condense out of the gas at different distances from the star and affect planetesimal composition. After a few million years (and again with a large intrinsic diversity), protoplanetary disks dissipate through this combination of accretion, photo-

evaporation, and planet formation. The end-state is a ► [debris disk](#) composed of second-generation dust created by planetesimal collisions in a gas-poor system.

The next section, “[Basic Methodology](#),” introduces the main diagnostic tools used to study protoplanetary disks. The middle section, “[Key Research Findings](#),” discusses our current understanding of these objects. The final section, “[Future Directions](#),” lists the most important open questions that current and planned telescopes may address in the coming decade. This contribution focuses on disks around low-mass stars with masses ~ 0.1 – 2 Msun. Disks have been detected around more massive stars, with spectral types O and B, but less is known about them due to the rarity of these objects and their short formation times. Although OB stars are astrophysically important, their strong ultraviolet radiation field, many orders of magnitude greater than the Sun, and their brief lives, < 1 Gyr, imply that any accompanying disks have lower astrobiological significance.

Basic Methodology

The closest young star forming regions are about 150 parsecs away from the Earth. For typical radii of a few tens of astronomical units, disks extend over only a few tenths of an arcsecond on the sky which makes them extremely challenging objects to image in detail, especially since they are much lower mass and much colder than their host star. Nevertheless, a remarkable amount can be learned about disks by studying their unresolved emission over a range of wavelengths or spectral energy distribution. Moreover, in the last decade, developments in instrumentation have made high-sensitivity, sub-arcsecond imaging possible. This has provided detailed images of disks and revolutionized our understanding.

Observational Diagnostics

Although dust makes up only 1% of the (initial) mass of a protoplanetary disk, its ► [continuum](#) emission offers a powerful observational probe of the presence of disks and their structure. The

temperature of dust grains varies widely across a disk ranging from their sublimation point at 1000–1500 K in the inner regions at a few stellar radii to 10–20 K at tens of au in the midplane where radiation is almost fully attenuated. The peak of the thermal radiation therefore varies from about 2 to 300 μm from the hottest to the coolest regions, respectively. Ground-based telescopes can detect the near-infrared ($\sim 1\text{--}3\ \mu\text{m}$) emission from the inner disk and the tail of the modified [blackbody](#) at wavelengths longer than about 0.3 millimeters. At intermediate wavelengths, 3–300 μm (the mid- and far-infrared), the Earth’s atmosphere is bright, and space-based platforms are required. Small dust grains also scatter and absorb light, most efficiently at short wavelengths, and high contrast images reveal the disk surface.

The other 99% of the disk that consists of gas is, counter-intuitively, much more difficult to detect. Most of the disk is too cold for the main gas constituents, molecular hydrogen and helium, to emit (although the directly irradiated surface may produce detectable hydrogen lines in the near-infrared and ultraviolet). Instead, rarer molecules are used to trace the gas conditions, such as CO and its [isotope](#) counterparts, that are excited at the densities and temperatures in disks and which produce [spectral lines](#) at millimeter wavelengths.

Spectral Energy Distribution

One of the most basic tools for determining the structure of a protoplanetary disk is a plot of the amount of energy that it emits as a function of frequency, known as the spectral energy distribution (SED). This is typically plotted in logarithmic axes as $\log(\nu F_\nu)$ versus $\log(\nu)$, where F_ν is the observed specific flux in a narrow frequency band around the observing frequency ν . In such a plot, peaks of similar height provide similar contributions to the total radiated energy. Other common ways to plot the SED are $\log(\lambda F_\lambda)$ versus $\log(\lambda)$, which is the equivalent expression in terms of observing wavelength λ , or $\log(\nu L_\nu)$ versus $\log(\nu)$ where L_ν is the specific [luminosity](#) or flux corrected for the source distance. A schematic showing which part of a

disk produces different parts of the SED is shown in Fig. 1.

The shape of the SED reflects the temperature distribution of the dust (since the emission from hotter material peaks at shorter wavelengths), which in turn depends on the location of the dust (Adams et al. 1987). Assuming vertical hydrostatic equilibrium, the location and the temperature of the gas and dust are closely linked. In this picture, the gas provides the pressure, while the small dust grains are largely responsible for the energy balance through the intercepted stellar radiation and their own continuum emission. To a lesser extent, other heating mechanisms (e.g., through the photoelectric effect or cosmic rays) and molecular or atomic line cooling may be relevant in some regions of the disk. With detailed measurements of the SED, a self-consistent model for the disk can be fit and the underlying disk structure obtained.

Imaging

Imaging has been crucial to advancing our understanding of protoplanetary disks in the last decade. The first images (and consequently the first direct detection) were made by the Hubble Space Telescope ([HST](#)) toward disks in the Orion star forming region which fortuitously lay in front of a bright background created by hot ionized gas. Dust absorbs this optical light and the disks therefore appear as silhouettes against the background. Analysis of the HST images provided disk sizes and a lower limit to their dust mass and revealed photoevaporation of gas from their surface. These objects were dubbed “proplyds” as a shorthand for protoplanetary disk (O’Dell et al. 1993), but this term is not generally used for disks that are not seen in silhouette.

Most disk images have since been made through high-resolution imaging of their emission at millimeter wavelengths. This has been achieved through [interferometry](#) whereby multiple radio telescopes are linked together over baselines ranging from hundreds of meters to many kilometers in length (ALMA Partnership et al. 2015). This technique does not require a particular arrangement of the disk and background and has opened up the investigation of hundreds of disks in

Protoplanetary Disk, Fig. 1 A schematic of a protoplanetary disk and its SED. The left-hand side of the disk shows dust processes that are discussed in Key Research Findings. The right-hand side shows the temperature and compositional profile. The hot dust in the inner disk produces near-infrared excess emission above that produced by the stellar photosphere shown in red. The flared

structure results in direct illumination of the disk surface at intermediate radii of a few to tens of au which produce strong mid- and far-infrared emission. The emission becomes optically thin at millimeter wavelengths and reveals large grains in the cold disk midplane. (Top image credit: Henning and Semenov (2013))

multiple star-forming regions with different ages and in different environments. Furthermore, the strength of the continuum and spectral line emission relate to the dust and gas mass respectively, and observations of different molecules can resolve chemical variations in the disk. Near-infrared interferometry reveals details of the hot dust at the star-disk interface, though the fidelity of such images is limited by the small number of baselines.

Driven by a broad astronomical need, high contrast adaptive optics imaging at near-infrared wavelengths on large ground-based telescopes has provided spectacular images of disks in recent years. In this case, the images map the light from the central star scattered by small dust grains in

the disk. This shows the disk surface and details therein and, in one clear case to date, newly forming planets. The combination of near-infrared scattered light and millimeter imaging, illustrated in Fig. 2, reveal different components of a disk and is a powerful technique to reveal internal processes.

Key Research Findings

Disk Incidence and Lifetime

The most sensitive way to determine whether a disk is present around a young star is to search for excess emission above the stellar photosphere at short wavelengths. Even very small amounts of

Protoplanetary Disk, Fig. 2 Two images of the IM Lup disk. The left panel shows scattered light at $1.6\ \mu\text{m}$ from small dust grains suspended in the gas. The bright emission comes from the upper layers of the flared surface. The central dot shows the location of the central, bright star that has been occulted in the optical path. (Image credit: ESO/H. Avenhaus et al./DARTT-S collaboration). The

right panel shows, on the same spatial scale, thermal dust emission at $1.3\ \text{mm}$ from much larger grains that lie in the disk midplane. Their extent is much smaller than that of the gas due to radial drift. The spiral structure may be due to disk self-gravity or torques from an unseen planet. These ALMA observations were published by Andrews et al. (2018)

dust close to a star, less than a lunar mass, will produce detectable emission in the near- or mid-infrared bands. This method works for individual stars but finds its true power when observing ► [stellar clusters](#) that can be observed together such as with infrared cameras on the ► [Spitzer space telescope](#). In color-color plots of the flux ratios at different wavelengths, equivalent to their difference in the ► [magnitude](#) system, the locus of stars with excess infrared emission is well separated from either field (► [“Main Sequence”](#)) stars or pre-main-sequence stars without excess. This way, the proportion of stars surrounded by disk material can be derived (Evans et al. 2009).

Since the age of a cluster can also be estimated more accurately than for individual stars, infrared surveys show how common disks are and their average lifetime. In the youngest clusters, with ages less than 1 Myr, the disk fraction (relative number of stars with excess emission) is over 80%. However, the stars without disks are close binary systems which are dynamically hostile places. Consequently, it appears that disks are essentially ubiquitous around young single stars.

Disk lifetimes vary from star to star, however, and the disk fraction decreases to less than 10% in old clusters with ages greater than 10 Myr, following an approximately exponential dependence with a half-life of 2 Myr.

Composition and Mass

Disks are composed of dust and gas from the interstellar medium. The dust originated in the winds from evolved (► [“Red Giant”](#)) stars and is mostly made of graphite and silicate minerals olivine, pyroxene, and forsterite in both crystalline and amorphous forms. In the cold interiors of the disk, these grains seed the freeze-out of volatiles from the gas and become surrounded by icy mantles. The various dust components produce broad spectral features in the mid- and far-infrared; they were observed by the ► [Infrared Space Observatory](#), ► [Spitzer space telescope](#), and ► [Herschel mission](#) and will be a major focus of study with the James Webb Space Telescope (► [“JWST”](#)).

Whereas infrared observations are very sensitive to the presence of dust, they cannot measure

how much there is since the emission saturates at the blackbody value. To measure the capacity of a disk to form planets necessitates measurements of its mass and requires observations at millimeter wavelengths where the emission has lower optical depth, generally less than one in all but the densest regions. In this regime, the continuum luminosity is directly proportional to the total dust mass with a temperature dependence through the blackbody function and an emissivity factor that converts the emitting surface area of a dust grain to its mass. The emissivity can be modeled using Mie theory or directly measured through laboratory experiments and depends on the composition, size, and shape of the grains. Because the grain properties are not precisely known and vary with location in the disk, dust mass measurements generally have a systematic uncertainty of about 3. The largest and most sensitive millimeter observatory, the Atacama Large Millimeter Array (ALMA), routinely achieves dust mass sensitivities of a Martian mass ($0.1 M_{\text{Earth}}$) in nearby star-forming regions. At this level, most (but not all) young stars with infrared excesses are detected. Those that are detected span a wide range in mass, with an approximately log-Normal distribution and dispersion of a factor of 10. The brightest, most massive disks have dust masses greater than $100 M_{\text{Earth}}$. The mean disk mass scales approximately linearly with the host stellar mass, but the large dispersion ensures that some low-mass stars have relatively high-mass disks and vice versa. The dust mass declines with time from a median $\sim 3 M_{\text{Earth}}$ in young regions < 3 Myr old to $\sim 0.3 M_{\text{Earth}}$ in relatively old regions with ages ~ 5 – 10 Myr. These values are all much lower than the amount of solid material in the solar system, $\sim 30 M_{\text{Earth}}$, likely because the observations are not sensitive to large particles that emit relatively weakly in proportion to their mass. The implication, discussed further below, is that most dust grains have grown by more than three orders of magnitude, from the sub-micron smoke-sized particles found in the interstellar medium to millimeter sizes of sand grains or hailstones, on Myr timescales.

The gas initially makes up 99% of the disk mass and is composed almost entirely of hydrogen

and helium. At the low temperatures and high densities of disks, the gas is predominantly molecular, although there are very small amounts of photodissociated and photoionized gas very close to the star and in a thin layer at the surface. The dominant species, H_2 , is very difficult to detect due to its symmetry and consequent lack of rotational dipole transitions. Warm H_2 emits weak quadrupole transitions in the mid-infrared, and energetic stellar radiation can excite vibrational and electronic transitions, but these are all limited to small and specific regions of the disk and do not relate to the total gas mass. Helium is effectively invisible but is well mixed with H_2 at its cosmic abundance and chemically inert.

The Herschel Space Observatory provided a unique opportunity, but with a limited lifetime that has now passed, to observe a far-infrared rotational line of deuterated molecular hydrogen, HD, which allowed the gas mass to be measured in a handful of disks. A complementary indirect method is to use estimates of the mass accretion rate from the disk onto the young star, measured through a variety of techniques from the ultraviolet to the infrared, multiplied by its age. The uncertainty in these methods is at least a factor of 3 but shows that many disks exceed the minimum mass solar nebula (MMSN) $\sim 0.01 M_{\text{Sun}}$.

Only trace amounts of C, N, O, and other elements are present in the gas and have been detected as simple molecular species such as CO, HCO^+ , H_2CO , CH_3OH , CN, HCN, and N_2H^+ through near-infrared and/or millimeter spectroscopy. The near-infrared lines originate in the inner disk and the millimeter lines from the outer disk but only in a relatively warm layer between an upper photodissociation layer and the cold midplane where ices form. Unlike the interstellar medium where CO and isotopic counterparts, ^{13}CO and C^{18}O , are a useful proxy for measuring gas masses, this does not appear to hold in protoplanetary disks. It is thought that mixing between the cold and warm disk layers in the outer disk may lock volatiles onto dust grains that settle, grow, and remain in the disk midplane. Consequently, disk CO abundances appear to be much lower than in molecular clouds and likely decrease with time.

The strong temperature gradient in disks leads to freeze-out of different molecules at different locations from the star. Water is almost completely absent in the gas phase beyond a few au where temperatures drop below 100 K, but CO remains in the gas phase over a much larger region of the disk where temperature is above 20 K. The interplay between the solid and gas components across these snowlines (and others such as CO₂) produces a rich chemistry that can be resolved in ALMA disk images and which may affect planetary composition in measurable ways through the C/O atmospheric ratios.

Dust Grain Growth

The low levels of dust emission, despite the abundance of planets, are an indirect indication that observations are missing the bulk of the solid mass in protoplanetary disks. Mie theory tells us that observations at wavelength λ are most sensitive to grains where $2\pi a \sim \lambda$. For a size distribution where the number of (spherical) grains with radius a scales as $n(a) \sim a^{-3.5}$, as expected in basic models of dust evolution through collisional aggregation and fragmentation, the cumulative mass is dominated by the largest particles which are relatively inefficient emitters per unit mass. Conversely, observations at longer λ can reveal the presence of larger grains. In practice, this is studied by measuring the power law index of the SED at millimeter wavelengths ($\nu = 300$ GHz), $F_\nu \propto \nu^{2+\beta}$, where $\beta = 0$ represents blackbody emission (in the Rayleigh-Jeans limit). Dust in the interstellar medium has $\beta \sim 1.7$, whereas protoplanetary dust has a significantly lower $\beta < 1$ which indicates more efficient emission at longer wavelengths due to larger grains. Thermal emission has been detected out to centimeter wavelengths indicating that grains have grown well beyond millimeter sizes. Such growth is promoted in disks by the high densities, low turbulence, and icy mantles that increase the sticking coefficient.

Although grain sizes of a millimeter are still many orders of magnitude smaller than a planetesimal, it is sufficient to have a profound physical effect. The grains are now massive enough that they have a significantly lower velocity dispersion than the gas and no longer feel its pressure. The

density and temperature in the disk decrease away from the star which creates a pressure gradient that opposes gravity and causes the gas to orbit slightly (less than a percent) slower than the Keplerian speed of the dust. Consequently, the larger dust grains feel a headwind, lose angular momentum, and drift radially inward (Weidenschilling 1977). They are similarly not hydrostatically supported and vertically settle to the midplane. These aerodynamic effects concentrate the solids in a critical first step toward planet formation. Dust grains that are large enough to decouple from the gas are known as “pebbles” although they might more closely resemble snowballs since the resolution of most observations is beyond the water snowline.

Structure

The structure of a protoplanetary disk refers to how its density, temperature, and composition vary with radius and scale height. Based on their SEDs and direct imaging, disk structures are generally well described by the theory of steady-state accretion disks, at least on scales greater than about 10 au. The theory is governed by a small number of conservation laws: conservation of mass dictates that, at every radius, the rate at which mass flows inward (or outward) is balanced by the amount of mass moving in from larger (or smaller) radii. Conservation of angular momentum dictates that the rate of change of the angular momentum at a given radius is balanced by the amount of angular momentum carried in (or out) of that radius by matter flow plus the amount of angular momentum that is transferred to material at adjacent radii by viscosity. The latter quantity relates the amount of torque that two adjacent radii exert on each other due to the gradient of angular velocity, or shear, between them. Viscosity causes fast-moving material close to the star to slow down while accelerating matter at larger radii, resulting in an outward transfer of angular momentum and an inward flow (accretion) of matter to smaller radii.

Ordinary molecular viscosity is far too small to match the observed disk accretion rates, and the source of viscosity remains unknown. Possibilities include turbulent mixing and

► **magnetohydrodynamic** instabilities. It is generally modeled as a free parameter following the Shakura and Sunyaev (1973) α prescription where viscosity, $\nu = \alpha H c_s$, for a disk hydrostatic scale height H and sound speed c_s . For a radial variation, $\nu \propto r^\gamma$, the surface density (mass per unit surface area) follows a power law form, $\Sigma(r) \propto r^{-\gamma}$, out to an exponentially truncated edge. Typical values between $\alpha(10\text{au}) = 10^{-4}$ – 10^{-2} and $\gamma = 0$ – 2 match the observed range of disk emission profiles and accretion rates. By 2020, about 200 disks had been resolved at millimeter wavelengths with radii ranging from 10 to 500 au where the radius is defined to include 90% of the total flux of the source. Most disks are at the small end of this range, near current resolution limits, but most detailed studies naturally focus on the rarer, largest objects. For these disks, the (millimeter sized) dust surface density at 100 au ranges from 10^{-2} to 10 kg m^{-2} .

The vertical disk structure follows from the radial density distribution and the assumption of vertical hydrostatic equilibrium, resulting in an exponential drop off of density with height above the midplane. For a geometrically thin disk, the temperature decreases with distance from the star as both the distance and the angle of incidence of the stellar radiation increase. However, the stellar gravity also decreases with distance, and the result is a scale height that increases with radius and a disk that is no longer perfectly thin. This raised surface intercepts more light,

causing the temperature to drop off less steeply with radius. This in turn causes the scale height to increase faster than the radius, and the disk starts to flare. Disk flaring naturally accounts for the bright mid- and far-infrared emission observed in disks. The scale height (of gas and small dust grains) increases with radius with typical values for the power law index ~ 1.3 – 1.5 and aspect ratio ~ 0.05 – 0.1 at 10 au, though there also exist some very cold disks that are much flatter.

One of the most exciting recent developments is the high-resolution imaging of protoplanetary disk substructures. These include rings, central holes, spirals, and arcs. Figure 3 shows a montage of ALMA 1.3 mm continuum maps at a resolution of 3 au. Even though only a few dozen disks have been imaged at this resolution so far, there is a remarkable diversity of structures. Rings are found at all radii and vary from narrow unresolved features to broad. Similarly, central holes range from the resolution limit to more than 50 au. Spirals are generally two-armed but range in tightness. Arcs extend from a few to over 180 degrees. The contrast of these features relative to the background varies substantially; sometimes they are seen in millimeter wavelength emission from large grains in the disk midplane, other times in scattered light from small grains in the upper atmosphere.

The basic physical explanations for these features is dust concentration in localized regions of high pressure. Just as the overall outward pressure

Protoplanetary Disk, Fig. 3 High-resolution ALMA images showing the variety of observed disk substructures: rings, arcs, central holes (and an inner disk). The horizontal line in the lower left of each panel is $0.1''$ across

corresponding to about 15 au at the distances of these sources. These data were originally published by Andrews et al. (2018) and Cieza et al. (2021)

gradient counteracts gravity to produce sub-Keplerian gas speeds and radially inward dust drift, a reversal at smaller radii would create super-Keplerian gas speeds and a tailwind on the solids that pushes them outward. Thus, millimeter- and larger-sized grains can be trapped in radial zones producing the observed rings. There are many (magneto-)hydrodynamical processes that can cause moderate ($\sim 20\%$) pressure variations in the gas that then lead a much stronger contrast in the density distribution of large dust grains. The concentration of solids can reduce local gas-to-dust ratios to unity whereupon the dust begins to dominate the dynamics and ultimately produce planetesimals (Chiang and Youdin 2010). Once formed, planets themselves produce pressure variations in the gas and can seed additional substructures, generally with an azimuthal dependence that would appear as spirals. Massive planets, several times that of Jupiter, or nearby stars, produce strong torques on the disk and can carve out gaps, central holes, and wide spirals.

Most high-resolution observations are of the dust components as they produce emission over a wide continuum which produces a much stronger signal than a narrow spectral gas line. Nevertheless, CO observations reveal the size of the gas disk and substructures within. The CO emission always extends beyond the millimeter dust, but this is partly due to its higher optical depth. In many cases, the difference is greater than a factor of two and confirms that the dust has radially drifted inward. Similarly, features such as rings and spirals in the gas generally have a lower contrast than those seen in the dust due to the stronger reaction of large grains to pressure perturbations. Different molecules can have different morphologies due to the chemistry, reflecting enhanced formation or destruction across snowlines and photodissociation (Öberg and Bergin 2020).

Kinematics

Millimeter-interferometric observations of the spectral lines from CO (and other molecular species) reveal the projected radial velocity at different locations in the disk. The motions are

dominated by Keplerian rotation with angular velocity, $\Omega \propto r^{-3/2}$, which allows the mass of the central pre-main sequence star to be accurately determined. The rotation is highly ordered with very low levels of ► [turbulence](#), generally below the thermal sound speed, $c_s \sim 0.1 \text{ km s}^{-1}$.

The high sensitivity and resolution of ALMA has led to more detailed studies of disk kinematics and investigations of radial and azimuthal flows related to accretion, substructures, and planet formation. A promising avenue is to search for localized deviations from Keplerian rotation that can detect sub-Jupiter mass planets and determine their mass and orbital radius.

Formation and Evolution

Disks are expected to form almost instantaneously as a molecular core gravitationally collapses. The envelope surrounding the growing protostar dominates the emission in the first ~ 0.1 Myr, limiting our knowledge of disk properties at these early times. Nevertheless, ALMA has mapped flattened rotating structures around the most deeply embedded, youngest protostars, and molecular lines from shocks where the infalling core hits the nascent disk have been identified in the mid-infrared. Ongoing work aims to study larger numbers of young disks in more detail and address questions about how fast they grow, whether instabilities produce massive accretions bursts known as FU Orionis events, and whether grain growth receives a head start during these early phases.

After about 0.5 Myr, the core has dissipated, and the disk, now around an optically visible star, is no longer growing and viscously evolves. The infrared excess decreases with time such that half the disks disappear within ~ 2 Myr, a half of the rest (i.e., one quarter of the initial) in the next 2 Myr, and so on. Based on exoplanet statistics, at least half the disks form planets. With a few exceptions, the disk emission decreases independently of wavelength indicating that the inner and outer disks disappear roughly simultaneously. Theoretical models show that the surface density of a viscously evolving disk will decrease gradually with time until the accretion rate decreases below the photoevaporation rate from the star. At

that point, the gas is lost from the inner disk faster than it can be replenished from the outer disk and an inner hole develops. The stellar radiation then directly impacts the hole rim accelerating the evaporation rate such that the disk rapidly clears from the inside-out on a timescale of ~ 0.1 Myr (Clarke et al. 2001).

A few disks are caught during the short transition time to complete dispersal. Their SEDs exhibit a mid-infrared decrement due to the lack of warm dust grains close to the star, and high-resolution imaging reveals the centrally cleared hole. However, the converse is not necessarily true, and there are many disks with central holes that cannot be explained by photoevaporative disk clearing. In some cases, low levels of gas or dust are detected in the gap, and in others, there is a small inner disk apparent either from direct imaging or near-infrared excess emission. In a subset of these, the plane of the inner disk is misaligned with that of the outer disk causing detectable shadows in scattered light or occultations (dips) in the optical light curve. The best explanation is dynamical clearing by a companion in the disk. Stellar binaries can completely clear out the central region leaving a circumbinary disk. The well-studied GG Tau and CoKu Tau/4 systems provide excellent natural laboratories to test theories. Planetary mass companions are less efficient at clearing the disk and allow some material to flow through the cavity. High enough flows can then replenish the inner disk which may also be dynamically perturbed from the plane of the outer disk. Direct detection of a faint planet close to the bright star is challenging, but the morphology is so suggestive that these disks are compelling targets for study.

The environment also plays a role in protoplanetary disk evolution. Stellar encounters truncate disks though this is unlikely to apply on solar system scales in all but the very most dense young clusters. However, stellar groups with more than a few hundred members are expected to include one or more OB stars. These produce copious amount of ultraviolet radiation which can significantly accelerate disk photoevaporation many parsecs away. This affects the outer regions

of the disk, however, and its impact on planet formation in the inner regions is unclear.

Planet Formation

Since the first resolved images, less than 30 years ago, disk research has revealed many important steps in the planet formation process. The gas mass is sufficient to form solar system scale planetary systems, and the dust grains have grown from microns to millimeters such that they aerodynamically decouple from the gas. Vertical settling, radial drift, and trapping in pressure bumps concentrate the solids. A leading theory for the next step is the streaming instability where pebble clumps provide a lower cross section per unit mass to the gas headwind and therefore catch up and accrete other pebbles, continuing to grow to a gravitationally cohesive planetesimal. Tests of planetesimal formation models are best made through observations of Kuiper belt objects, but there is tentative support for rapid pebble to planetesimal conversion in disks through an upper limit to the optical depth of dust rings which may indicate a surface density threshold.

Disk structures such as partially filled central holes, misaligned inner disks, and spirals are strong evidence for unseen planetary mass companions. Deviations from Keplerian rotation are also compelling signatures. Direct detections are challenging because they require contrasts of four or more orders of magnitude at sub-arcsecond scales in the optical or near-infrared. However, just as circumstellar disks are relatively easy to detect on account of their large emitting area, circumplanetary disks may be easier to detect than the planets themselves. So far, ALMA searches have only been able to provide upper limits showing that such disks are either very low mass or very small, but it is likely only a matter of time before the first detection.

A major advance was recently obtained through observations of the PDS70 star, shown in Fig. 4, which shows a Jupiter mass planet lying in the cleared central hole of a disk (Keppler et al. 2018). Follow-up observations found a second planet at the edge of the dust ring. This system will hopefully only be the first of many to come. Their characterization

Protoplanetary Disk, Fig. 4 The first incontrovertible image of a protoplanet within a disk around a young star. Taken at $2.2\ \mu\text{m}$ with the SPHERE instrument on the ► [VLT](#), the light from the central K5 star has been occulted to allow the much fainter emission from the planet and disk to be seen. The planet, PDS70b, is 23 au from the star and

is estimated to be a Jupiter mass. It lies within a large central hole in the disk, which is seen in scattered light. Though not obviously apparent in this image, a second planet, PDS70c, was subsequently found in the bridge of emission between the disk and star. (Image credit: ESO/A. Müller)

will provide the critical link between disk properties and their planetary outcomes.

Future Directions

The study of protoplanetary disks is an area of intense current research in both observations and theory and has a bright future. Progress has accelerated due to advances in high-resolution imaging at multiple wavelengths leading to significant advances in our understanding of planet formation, the origin of the solar system, and the transport of volatiles from the interstellar medium to the inner disk. As with all astronomical fields, the pace of discovery is generally driven by instrumentation, and we anticipate major new results from JWST due to its great sensitivity and spectroscopic capabilities at mid-infrared

wavelengths. Of particular astrobiological interest will be observations of the disk organic content in the (future location of the) habitable zone.

ALMA has revolutionized our view of disks in the last few years and it has only just got started. As high resolution, detailed imaging becomes routine, we anticipate a wealth of new studies. These include an unbiased census of disk substructures to learn whether there is any dependence on host star, age, or environment. In tandem with ever more sophisticated modeling, structural and kinematic features will provide new constraints on super-Earth to Jupiter mass planets at orbital radii of a few to many au. More insights into disk chemistry will strengthen the connection with planetary composition. Circumplanetary disks appear to be fainter than simple model predictions, but the first secure detections will happen soon. In the near-infrared, ongoing upgrades to

adaptive optics systems on ground-based telescopes will achieve smaller inner working angles and greater contrast, providing higher fidelity images closer to the star which will likely provide more “Rosetta stones” of direct planet detections in young disks such as those in Fig. 4.

The ► [Square Kilometer Array](#) (SKA) will start its first science operations in the mid-2020s. With its promise of high sensitivity at centimeter wavelengths and sub-arcsecond imaging, it will detect pebbles with centimeter and larger sizes and complex organics in the gas. Finally, plans for the next-generation Very Large Array (ngVLA) would achieve tens of micro-arcsecond resolution at 3 mm wavelength in the 2030s, sufficient to hunt for disk structures created by young planets in the terrestrial planet-forming region of the closest disks.

Further Reading

There are two reviews of protoplanetary disk research in the Annual Reviews of Astronomy and Astrophysics series. The first, Williams and Cieza (2011), is a broad overview of disk evolution and, though many of the results have now been superseded by more recent ALMA data, still serves as a useful general introduction for beginning researchers. The second, Andrews (2020), discusses the emerging field of disk substructures with a focus on observations and modeling. A pedagogical reference for both students and researchers is the textbook on planet formation by Armitage (2020) that derives much of the physics of protoplanetary disks

Protoplanetary Disk Dead Zone

Avi M. Mandell
NASA Goddard Space Flight Center, Greenbelt, MD, USA

Definition

A dead zone is an annular region of a circumstellar disk where the local [viscosity](#) is essentially zero, leading to a negligible infall of disk material toward the central star. Viscosity is needed to remove the orbital energy and angular momentum from gas and dust in the disk, allowing material to spiral inward and accrete onto the central star (as observed in young stellar systems with known circumstellar material). The source of this disk viscosity is uncertain, but the most likely source is electromagnetic interactions between ionized species, known as the magnetorotational instability (MRI). Dead zones may be created when the local gas is insufficiently ionized to support the MRI. They can occur, for example, when the gas column density is large enough to protect the inner zones of the disk from ionization by cosmic rays.

Protoplanetary Disk Instability

Avi M. Mandell
NASA Goddard Space Flight Center, Greenbelt, MD, USA

Synonyms

[Gravitational instability](#)

Definition

Disk instability refers to a model for giant planet formation in which a region of a circumstellar disk becomes dense and cool enough to be unstable to gravitational collapse, resulting in the formation of a gaseous protoplanet. The disk instability mechanism for giant planet formation has been postulated as a mechanism for forming massive [giant planets](#) on short timescales (1 Ky–1 My), which may be required to form gas giant planets in short-lived disks and disks with a low metal abundance. However, it is unclear whether real circumstellar disks can cool sufficiently quickly to initiate gravitational disk instabilities before the gaseous disk dissipates. The quantitative measure of a disk's ability to become gravitationally unstable is the Toomre Q value.

Protoplanetary Disk Midplane

Avi M. Mandell

NASA Goddard Space Flight Center, Greenbelt,
MD, USA

Definition

The disk midplane corresponds to the region of a circumstellar disk where the vertical density distribution peaks. The midplane is thought to be the coldest region of the disk, due to the inability of stellar radiation to penetrate deeply. The low temperatures and high densities lead to the fastest growth timescales for ► [planetesimals](#) and result in planets with coplanar orbits (if no scattering or inclination pumping occurs).

Protoplanetary Disk of Second Generation

Avi M. Mandell

NASA Goddard Space Flight Center, Greenbelt,
MD, USA

Synonyms

[Debris disk](#)

Definition

A second-generation ► [protoplanetary disk](#) is a disk of circumstellar material created by the

destruction of young planetary bodies during the late stages of planetary formation. Such disks are commonly called ► [“debris disks”](#). Debris disks have been detected around stars with ages from 10 My up to billions of years, and they usually contain approximately a lunar mass of material in small grains. The presence of planets is usually unknown, though several giant planets have now been directly imaged in debris disks.

► [Protoplanetary disks](#) (PPDs) surrounding young stars are short-lived ($\sim 1\text{--}10$ Myr), compact ($\sim 10\text{--}1,000$ AU) rotating reservoirs of gas and dust. Disks are believed to be the birthplaces of planetary systems, where tiny grains are assembled into pebbles, ► [planetesimals](#), and eventually planets, asteroids, and comets. The evolution of gas and grain growth in disks is related to the redistribution and transport of angular momentum, which is thought to be governed by

magnetohydrodynamical turbulence. The intense high-energy radiation from one or more young stars and strong spatial and temporal variations in the physical conditions (accretion rate, temperature, density, grain sizes) make a variety of chemical processes active in protoplanetary disks. In PPDs, simple molecules are rapidly produced in the gas phase via ► [ion-molecule](#) and ► [neutral-neutral reactions](#). The more complex (organic) species in disks are slowly synthesized on and in the icy mantles of dust grains and later are either released to the gas phase or become trapped inside growing dust aggregates.

Overview

It is particularly important to understand under what conditions prebiotic molecules and their simpler “building-block” precursor species could be produced and how they evolve during the star- and planet-formation process. Powerful ground-based and airborne observational facilities and robotic space missions have recently become available, which have permitted the chemical composition of nearby star-forming regions to be sensed remotely and pristine Solar System materials to be collected in situ. In addition, increasing computer power makes sophisticated simulations of the interstellar chemistry feasible. The progress is particularly rapid in understanding the physics and chemistry of protoplanetary disks around young stars – analogs of our Solar System at the age of several million years.

Many protoplanetary disks surrounding young Sun-like stars possess sufficient material, of order several Jupiter masses, to assemble planetary systems (e.g., Lin and Papaloizou 1980; Payne and Lodato 2007; Williams and Cieza 2011). According to the modern paradigm of star formation, the collapse of a cold ► [molecular cloud](#) of several solar masses leads to formation of (a) protostar(s) surrounded by a compact, rotating, flattened structure, the protoplanetary disk. The protostar is initially still enshrouded by an envelope of cloud material. During a few million years of dynamical evolution, much of the prenatal

cloud material accretes on to the protostar, with some material ejected as a ► [bipolar outflow](#). After that, the outflow ceases and the newly born central star becomes visible.

Photospheric activity of the star drives intense, variable ultraviolet (UV) and X-ray radiation, leading to steady photo-evaporation and, after taking account of ongoing accretion, to dispersal of remaining disk matter (e.g., Gorti et al. 2009). The dense disk interior conditions are favorable for rapid agglomeration of submicron-sized dust grains into larger cm-/m-sized pebbles and rocks. During formation, they sediment toward the disk equatorial plane (► [“Protoplanetary Disk Mid-plane”](#)), eventually forming ► [planetesimals](#) and planets as well as ► [comets](#), or move inward due to gas friction and are accreted onto the star. The forming planets interact gravitationally with the surrounding gas, inducing asymmetric spiral waves and other substructures, and may even open gaps or clear central holes in disks (e.g., Fukagawa et al. 2004; Grady et al. 2013).

Molecules are important diagnostics of physical conditions in disks. Also, molecules are key heating and cooling agents of the gas, especially in the disk atmospheres. Dust grains determine the opacity of the disk medium to the stellar radiation and so shape the disk thermal and density structure. Ionization chemistry induced by high-energy radiation from (a) central star(s) or interstellar space and cosmic ray particles (CRPs) determines the strength of the coupling between the gas and magnetic fields, thus controlling the global disk dynamics via ► [turbulence](#).

Consequently, a strong time-dependent variation of temperature, density, and dissociating radiation intensity across a disk induces pronounced spatial gradients and leads to a rich chemistry in the gas phase and on the surfaces of dust grains. In this entry, we summarize *the major modern observational methods and theoretical paradigms* used to investigate disk chemical composition and evolution and present the most important results. Future research directions that will become possible with the advent of the Atacama Large Millimeter Array (► [ALMA](#)) and other forthcoming observational facilities are also discussed.

Basic Methodology

In the table and in the text that follows, we use the standard spectroscopic notation that specifies the ionization state by Roman numerals: I for a neutral atom (e.g., NeI for Ne), II for singly ionized (e.g., NeII for Ne⁺), etc. So far, astronomers have discovered about 160 molecular species (230 including isotopomers) in space (► [Molecules in Space](#)). These vary from simple radicals (e.g., CH⁺) to complex molecules like cyanopolyynes (e.g., HC₁₁N), ► [polycyclic aromatic hydrocarbons](#) (PAHs; up to C₆₀ and C₇₀), and organic molecules (e.g., CH₃OH, HNC, HCOOCH₃, HOCH₂CHO) as well as positive (e.g., HCO⁺) and negative (e.g., C₈H[−]) ions. Among these interstellar species, only a handful of molecules have been identified in disks through infrared (IR) and (sub)millimeter spectroscopy: H₂, HD, CII, NeII, FeI, OH, H₂O, CO (and isotopologs), CN, HCN, DCN, HNC, HC₃N, C₂H, C₂H₂, c-C₃H₂, CS, HCO⁺, H₂CO, DCO⁺, NH₃, and N₂H⁺ (Dutrey et al. 1997, 2007b; Kastner et al. 1997; Aikawa et al. 2003; Qi et al. 2008, 2013; Chapillon et al. 2012).

Solid materials detected in nearby PPDs via infrared spectroscopy include aliphatic and aromatic carbon-based materials (in unknown form), polyaromatic hydrocarbons (PAHs), amorphous and crystalline silicates of olivine and pyroxene stoichiometry, and molecular ices (like CO, CO₂, H₂O). The presence of various other organic compounds has also been inferred (e.g., Terada et al. 2007; Acke et al. 2010; Min and Flynn 2010; Henning and Meeus 2011; Teske et al. 2011; Aikawa et al. 2012; Bergin et al. 2013).

Another vital source of information about the pristine composition of solids at the verge of planet formation in the young Solar System are the studies of meteoritic materials and cometary samples and remote observations of active comets passing near the Sun (Ehrenfreund and Charnley 2000). An isotopic analysis of various primitive refractory materials allows us to discern the time of their condensation (radiogenic dating). In addition, petrological, mineralogical, and texture analyses constrain the timescales of the cooling of the freshly formed minerals and the physical

conditions (temperature, density) at which they have condensed out.

Unfortunately, a vast majority of volatiles have either vaporized during the formation and evolution of solids or have been lost due to further thermal processing in the meteorite parent bodies or during the sample preparation in the laboratory. A direct access to the composition of pristine ices and organics in cometary dust is possible via robotic missions, like the *Stardust* mission that collected and delivered to Earth the first dust samples from the comet *Wild 2* (Elsila et al. 2009; Wozniakiewicz et al. 2012). The Rosetta mission of the European Space Agency will deposit by November 2014 a lander and an orbiter on the comet 67P/Churyumov-Gerasimenko for detailed in situ analysis of the comet surface (http://www.esa.int/Our_Activities/Space_Science/Rosetta/Europe_s_comet_chaser).

(Sub)millimeter Observations

Dusty PPDs are transparent only when observed at wavelengths longer than $\sim 100\ \mu\text{m}$ (far-infrared/(sub)millimeter wavelengths). Since the dominant molecular component of the gas, H₂, does not emit observable radiation at (sub)millimeter wavelengths apart from high-temperature regions around the star (e.g., Bitner et al. 2007), other trace species and dust are used to study physical conditions in disks (Table 1). A unique tracer of the total gas mass is deuterated molecular hydrogen, HD, whose fundamental rotational transition at 112 μm has been recently detected with the *Herschel* satellite toward the nearest protoplanetary disk around TW Hya (Bergin et al. 2013).

At (sub)millimeter wavelengths, there are no prominent solid-state features, but the observed continuum emission allows us to estimate dust disk mass and infer the presence of large, millimeter-sized grains. Since dust opacities at these wavelengths and the dust/gas mass ratio are poorly known, the constrained disk mass is subjected to large uncertainties.

By contrast, the (sub)millimeter spectral window is rich in molecular rotational lines. It is not fully accessible from the ground due to atmospheric absorption, primarily by water and

hydroxyl (OH). Single-dish telescopes like the IRAM 30-m antenna (ESO, Spain), the APEX 12-m antenna (ESO, Chile), and the 15-m James Clerk Maxwell Telescope (UK, Hawaii) are used to survey PPDs in lines of potentially detectable species. Although lacking the spatial resolution to resolve the disks, single-dish molecular spectra allow astronomers to constrain disk-averaged amounts of emitting molecules (column densities) and roughly estimate disk orientation and temperature.

The sub-arc-second imaging required to resolve PPDs is provided by antenna arrays such as the Plateau de Bure Interferometer (France), the Submillimeter Array (USA), and the Combined Array for Research in Millimeter-wave Astronomy (USA). Since 2013, observations have begun with the much more powerful Atacama Large Millimeter Array (► [ALMA](#), Chile), a joint project of Europe (ESA), the USA, and Japan. Until the advent of ALMA, such studies were scarce and restricted to outer disk regions ($r > 30$ AU). The objects best studied thus far included DM Tau, LkCa 15, AB Aur, TW Hya,

MWC 480, HD 163296, and HD 100546. In PPDs, most molecular lines are optically thin and so their observed spectral line shapes result from a combination of molecular spatial distribution, excitation conditions, and transport of the line radiation through the disk. The molecular spectra yield unique information on disk kinematics and geometry, temperature and density structure, and the intensity of dissociating and ionizing radiation.

The disk size and orientation can be constrained directly by the geometry of dust emission and integrated line intensity maps (e.g., ^{13}CO 1–0); see Fig. 1. Next, the PPD kinematics can be recovered by analyzing the velocity at various points in the disk from the Doppler shift of molecular lines. By high-resolution observations of heavy molecules like CS and HC_3N , which have narrow intrinsic and thermal broadening of the line profiles, one can constrain the levels of gas turbulence in outer disk regions (Guilloteau et al. 2012, see also Hughes et al. 2011). For molecules with high dipole moments and regular energy-level structure (e.g., CS, H_2CO , HC_3N , HCO^+),

Protoplanetary Disk, Chemistry, Fig. 1 The DM Tau disk imaged with the Plateau de Bure Interferometer in the HCO^+ 1–0 line with $1.5''$ resolution. Shown are the integrated line intensity (*top left*) that increases toward the central star (indicated by cross), the velocity map (*right*

top) that reveals a “butterfly”-like symmetric pattern typical of rotating disks (*bluer* side approaching, *greener* side receding), and the line width distribution (*bottom left*), where velocity increases toward the disk center due to Keplerian rotation ($V(r) \propto r^{-1/2}$)

multi-transition observations constrain the gas density distribution, since higher energy transitions require higher densities for excitation. The thermal disk structure is derived from the strength of optically thick CO lines (e.g., ^{12}CO 1-0, ^{12}CO 2-1, etc.), which trace different disk heights. The line shapes of CO [isotopologs](#) carry information about both temperature and molecular density distribution, and these can be used to derive the disk surface density profile. Ratios of line intensities for a parent molecule and its photodissociation product (like HCN and CN) reflect the strength of the disk irradiation by high-energy UV photons. However, for larger molecules, the population is divided over many energy levels, leading to lower line intensities and making it

harder to detect and resolve the spectra of such species. Furthermore, the spectra of molecules with a complex level structure, like water, are particularly difficult to analyze. Therefore, to fully interpret interferometric spectra of a given molecule, one has to construct computational models which take into account many disk properties, kinematics and geometry, density and thermal structure, and radial and vertical molecular distributions, and employ a line radiation transport model to fit the observed data iteratively.

Infrared Observations

At IR wavelengths, spectral features associated with various components of solid dust particles are evident, as are the rotational-vibrational and

vibrational bands of gas-phase species (e.g., due to stretching and bending of molecular bonds). Atmospheric transparency windows permit limited observations from the ground, and so spaceborne telescopes are essential for full spectral coverage. From analysis of these data, we can constrain the local temperature and amount of absorbing/emitting material on the line of sight. The ratio between near-IR and far-IR dust emission is used to indicate an evolutionary phase of a disk, because in an old system, dust grains may grow so big in the dense inner region that the near-IR flux disappears, while the far-IR excess emission is still characteristic of cold, submicron-sized grains (Bouwman et al. 2008).

The inner, $\sim 1\text{--}20$ AU planet-forming disk regions only recently became accessible, with the advent of near- and mid-IR ground-based interferometers (such as those at the Palomar Observatory, W.M. Keck Observatory, and Very Large Telescope Observatory) and the launch of space observatories (the ► [Infrared Space Observatory](#), ► [Spitzer Space Telescope](#), and ► [Herschel Mission](#)). IR interferometers do not retain the phase information of the detected signal and thus require sophisticated analysis of the acquired data based on template disk models to constrain the geometry and mass of the hot dust region. The (ro-)vibrational emission/absorption molecular lines and solid-state emission bands of ices as well as a variety of silicates and polyaromatic hydrocarbons (► [PAHs](#)) and simple organics have been detected in disks (van Dishoeck 2004; Pontoppidan et al. 2005; Lahuis et al. 2006; Pascucci et al. 2007; Bouwman et al. 2008; Zasowski et al. 2009; Acke et al. 2010; Salyk et al. 2011; Teske et al. 2011; Fedele et al. 2012). Identified species include H_2O , C_2H_2 , HCN, OH, NeII, and some others; from their spectra local temperature, FUV intensity and molecular concentrations can be derived.

The major components of dust grains in disks are amorphous and crystalline silicates (e.g., MgSiO_3 and Mg_2SiO_4), troilite (FeS), metals and oxides, quartz, C-containing compounds, and water/CO ices (Pollack et al. 1994). Metals do not have any distinct spectroscopic signatures, while only certain carbon-bearing compounds

show generic aliphatic and aromatic features, making it difficult to identify their exact composition (which is likely a mixture of ► [hydrogenated amorphous carbon](#), diamonds, ► [PAHs](#), and polymerized organic materials). Studies of chemical and petrological compositions of meteorites and samples of cometary materials seem to be the only possibility to try to understand the properties and composition of the pristine organics that can be present at the planet-formation stage of the disk evolution (Ehrenfreund and Charnley 2000).

Key Research Findings

Outer Disk: (Sub)millimeter and Far-Infrared Observations

High-resolution interferometric observations at submillimeter and millimeter wavelengths have allowed the chemical composition and physics of the outer regions (beyond 30–50 AU) to be examined in several nearby PPDs. Observations at the Plateau de Bure Interferometer (PdBI; France), the Very Large Array (USA), and the Australia Telescope Compact Array (ATCA) at millimeter and centimeter wavelengths show evidence for significant grain growth up to cm sizes in disks (e.g., Rodmann et al. 2006; Cortes et al. 2009; Guilloteau et al. 2011). The IR spectroscopic surveys of young stars in stellar clusters of various ages have placed tight constraints on typical dispersal times of dense ► [protoplanetary disks](#) of ~ 5 Myr, while their inner, planet-forming zones ($< 10\text{--}100$ AU) are cleared of submicron-sized dust grains within only ~ 1 Myr (Fedele et al. 2010).

Prominent low- and high-energy CO rotational lines are readily excited by collisions at densities of $\sim 10^3\text{--}10^5\text{ cm}^{-3}$. The ^{12}CO lines are optically thick, and their intensities measure kinetic temperature in the disk upper layer. The lines of less abundant ^{13}CO and C^{18}O are typically optically thin or partially optically thick and are sensitive to both temperature and the CO column densities through the disk. Strong CO lines are suitable for accurate determination of disk kinematics, orientation and geometry, and hence the mass of

the central star. From interferometric observations, it has been found that measured disks radii appear the smallest for the dust continuum and progressively larger in the C^{18}O , ^{13}CO , and ^{12}CO lines, with typical values of ~ 100 – $1,000$ AU. Multi-line CO studies have revealed a clear sign of vertical temperature gradients in several disks, increasing from ~ 10 K at the midplane to ~ 50 K in the atmosphere region (e.g., Dartois et al. 2003; Qi et al. 2006; Piétu et al. 2007). The high surface temperature of the TW Hya disk as measured by the ^{12}CO ($J = 6-5$) line cannot be solely caused by the black body stellar radiation and requires an additional heating source, likely stellar X-rays (Qi et al. 2006). A number of protoplanetary disks with large inner “dust” holes, such as LkCa15, do not show temperature variation in the vertical direction and thus must have a peculiar structure. Dartois et al. (2003) and Piétu et al. (2007) have reported that a large amount of CO and other gas-phase molecules exist at ~ 10 – 15 K in the DM Tau disk, which contradicts the expectation that most of these molecules should reside on grains at such low temperatures. The recent interferometric observations of water vapor in the closest disk around TW Hya by (Zhang et al. 2013) determined the location of the “snow line” (the location where water ices is thermally evaporated, $T \sim 120$ – 160 K) and thus constrain the disk’s radial temperature distribution. In a similar study, (Qi et al. 2013) have observed the TW Hya and HD 163296 disks in lines of N_2H^+ and H_2CO and inferred the location of the “snow line” for CO, which is located far away from the central stars, where dust temperatures are below 20 K.

Molecules with larger electric dipole moments than CO require higher gas densities to excite emission, since collisional excitation must overcome radiative de-excitation in order for higher energy levels to be populated. An easily observable molecular species in disks is HCO^+ , which does have a larger dipole moment (3.92 D = Debye). The lower energy $J = 1-0$, $2-1$, and $3-2$ transitions of this ion (J is the rotational quantum number) are excited at densities of $\gtrsim 10^5 \text{ cm}^{-3}$ and are (partially) optically thin. This is one of the most abundant charged species in PPDs, the other being C^+ , which is not observable at

millimeter wavelengths. Due to its large dipole moment, HCO^+ is a good density probe, in addition to being a tracer of ionization degree (see Table 1). Another, less abundant observable ion in disks is N_2H^+ (3.37 D). The $1-0$ N_2H^+ line exhibits hyperfine splitting, and so from relative intensities of its individual components, one can reliably determine the **optical depth** of the line and constrain the N_2H^+ column density. Using these ions as probes, it has been found that the degree of ionization in disk interiors is $\sim 10^{-9}$ (one charged species per billion), in agreement with the derived cosmic ray ionization rate and predictions from disk chemical models (Qi et al. 2003).

The distribution and total amount of HCN and its dissociation product, CN, depend on the intensity and spectral shape of the high-energy UV radiation impinging into the disk (Bergin et al. 2003). The stronger the FUV flux, the higher the CN-to-HCN line ratio due to higher concentrations of CN and lower abundances of HCN. The observationally inferred elevated ratio of CN to HCN abundances indicates that the chemistry in PPDs is indeed affected by the stellar FUV radiation. Another radical observed in disks, C_2H , is sensitive to the X-ray luminosity of the central star, as higher flux of X-ray photons replenishes more of the elemental carbon locked in CO back into the gas phase, where it is quickly converted to light hydrocarbons (Henning et al. 2010). The recently detected cyclopropenylidene ($\text{c-C}_3\text{H}_2$) in the disk of TW Hya with the ALMA interferometer by Qi et al. (2013) seems to be another excellent tracer of the UV radiation intensity penetrating through disk upper layers.

Rotational lines of the less abundant CS and H_2CO are difficult to observe even in bright disks. The CS lines, excited at densities $n \sim 10^5$ – 10^7 cm^{-3} , have very narrow intrinsic widths and as such can be utilized to measure turbulent gas velocities in disks through the Doppler effect, as well as to discern disk density structure. The measured turbulent broadening is subsonic, with a typical microturbulent velocity of ~ 0.05 – 0.2 km s^{-1} (Hughes et al. 2011; Guilloteau et al. 2012). The simplest organic molecule, H_2CO , has a slightly asymmetric top

structure and serves as both a densitometer and a thermometer. It is partly produced on surfaces of dust grains and can also be used as a probe of the efficiency of surface chemical processes. Recently detected DCO^+ and DCN in TW Hya have abundances comparable to the abundances of their main isotopologs, HCO^+ and HCN (Qi et al. 2008), while the cosmic abundance ratio of D/H is only 10^{-5} . Their radial distributions in the TW Hya disk have been derived by Oberg et al. (2012) using the Science Verification ALMA data. While DCO^+ column density increases with radius in the disk, the DCN emission is more centrally peaked, indicating different pathways to deuterium fractionation in disks. It remains to be verified though whether such a large degree of deuterium fractionation is a heritage of pre-disk cold evolutionary phases in the parent [molecular cloud](#) or if these large D/H ratios can be produced in situ in PPDs.

A remarkably consistent finding is that gas-phase molecular abundances relative to molecular hydrogen are lower by factors of 5–100 compared to the values in the cold interstellar Taurus Molecular Cloud (Dutrey et al. 2007). This has been interpreted as a combination of intense UV and X-ray dissociation of molecules at elevated disk heights by the young central stars and proficient sticking of gas-phase molecules to dust grains in cold disk interiors, forming thick icy mantles.

The observations at far-infrared wavelengths with the *Herschel* space telescope probe molecular emission lines and solid-state bands of ices and silicates arising at distances of ~ 1 –100 AU in disks. The data are still being reduced and analyzed; here we report on major recent discoveries that have been published.

In a number of protoplanetary disk orbiting around Sun-like and more massive, hotter intermediate-mass Herbig stars, emission from hydroxyl (OH) has been detected. Combined with *Spitzer* observations of warm water, there is an apparent lack of water in the more heavily irradiated disks around Herbig stars, suggesting that H_2O in their upper inner disk regions can be severely dissociated (Fedele et al. 2013).

The non-detection of cold H_2O in DM Tau provided stringent upper limits to the amount of water vapor in the outer disk region. The low

amount of water vapor cannot be explained by modern astrochemical models. A plausible scenario is that a substantial fraction of water ice (the major reservoir of water) can be already locked in big grains that settled toward the mid-plane, unable to be photo-evaporated (Bergin et al. 2010). A higher amount of water vapor in the disk around another star, DG Tau, was inferred by Podio et al. (2013). Using an advanced disk physical and chemical model, they derived that the water emission stems from a hot region of ~ 600 K in the upper disk region, with a total amount of water vapor of $\sim 10^2$ – 10^3 Earth oceans (and 100 times more in the solid form).

(Hogerheijde et al. 2011) have successfully detected emission lines from both the ortho- and para-spin isomers of water in the disk around TW Hya. This ratio cannot be changed by radiative or collisionally induced transitions and can only be modified by chemical processes involving proton exchange. The ortho-para ratio (OPR) of water is thought to be determined by the temperature at which water ice formed on dust grains via hydrogenation of surface O and OH. Hogerheijde et al. have found that the ortho-para ratio for H_2O in TW Hya is 0.77, indicating low temperatures of the H_2O ice formation, ~ 15 – 20 K. Interestingly, this temperature seems to be lower than the temperatures derived from various OPR ratios measured in Solar System comets (~ 30 – 50 K; see Woodward et al. 2007; Bockelee-Morvan et al. 2009; Bonev et al. 2013).

A detection of pure HD rotational lines in the TW Hya disk allowed probing for the first time the total gas disk mass, as the HD/ H_2 ratio should not change much even in warm protoplanetary disks (Bergin et al. 2013). The inferred disk mass was larger than previously suggested, 0.05 solar masses, which is somewhat surprising for a ~ 5 million-year-old system.

Inner Disk: Infrared Spectroscopy

Results from the [Infrared Space Observatory](#) and the [Spitzer Space Observatory](#) have revealed the presence of a large amount of ice, [polycyclic aromatic hydrocarbons \(PAHs\)](#), and both amorphous and crystalline silicates in disks (e.g., Bouwman et al. 2008; van Dishoeck 2004;

Pontoppidan et al. 2005; Lahuis et al. 2006; Pascucci et al. 2007). The PAH features at $\sim 3\text{--}12\text{-}\mu\text{m}$ probe the intensity and shape of the incident radiation field and the density distribution in the disk. Only $\sim 10\%$ of PPDs around young Sun-like stars show aliphatic (C-H) and aromatic (C-C) PAH bands, and often these bands appear only in the outer disk zone (beyond $\sim 30\text{--}100$ AU). The small PAHs with unbound geometry (< 50 C atoms) are destroyed by the intense FUV and, in particular, X-ray stellar radiation, while bigger and compact PAHs do survive in PPDs. The PAHs remain in the gas phase only in dilute, ice-free upper disk regions and are frozen out in disk interiors. It is interesting to note that the $3\text{-}\mu\text{m}$ diamond emission tends to be centrally peaked in PPDs, which may indicate a high-temperature conversion of H-poor large PAHs into nano-diamonds.

A multitude of amorphous and crystalline silicates with varying Fe/Mg ratios and grain topology/sizes have also been detected (Bouwman et al. 2008). A striking result is that both the crystallinity fraction and the abundance ratio of forsterite/enstatite ($\text{Mg}_2\text{SiO}_4/\text{MgSiO}_3$) change across a disk. The fact that mid-IR features are characteristic of mostly iron-poor silicates implies their rapid condensation from the gas phase during transformation of a [molecular cloud](#) into a disk. Other metals like Fe and Ca are found as a component (often as sulfides) of glassy inclusions inside a silicate matrix in meteorites (see [GEMS](#)). The variety of observed silicate band profiles is due to various average sizes of emitting grains, implying that small submicron-sized particles and bigger, several micron-sized grains exist in PPDs.

Ices are present in the cold, outer disk region beyond the “snow line,” at temperatures below ~ 120 K ($r \gtrsim 20$ AU). These features are easier to detect in highly inclined systems. The major mantle component is water ice, with an abundance of about 10^{-4} (relative to the total particle density). Water ice is intermixed with other, more volatile ices of, e.g., CO, CO₂, NH₃, CH₄, H₂CO, and HCOOH (Zasowski et al. 2009). Typical abundances of these minor constituents are about 0.5–10% with respect to water. As it has

been revealed from the complex shape of icy features with substructures, a substantial part of these volatile ices can be chemically bound to grain surface sites (“chemisorbed”) and thus will remain frozen even at elevated grain temperatures and UV irradiation.

The detection of NeII line emission from several disks, as well lines from iron, sulfur, and argon, has confirmed theoretical predictions that the disk atmosphere is heavily ionized and superheated by the energetic photons. Detected rotational H₂ and (ro-)vibrational CO, CO₂, C₂H₂, and HCN as well as H₂O and OH lines trace a hot gas in the inner, planet-forming disk zone with $T \sim 300$ K (Lahuis et al. 2006; Salyk et al. 2008). The HCN-to-C₂H₂ ratio is a sensitive tracer of the UV/X-ray intensity or accretion rate inside an inner disk, while the easily populated CO lines allow us to constrain kinetic temperature. The rich chemical composition inside planet-forming disk zones suggests that many endothermic reactions with barriers become active there.

Theoretical Picture of Chemical Structure of a Disk

We present a general scheme of a PPD structure based on observational results and theoretical predictions in Fig. 2 (see, e.g., Aikawa and Herbst (1999), Willacy and Langer (2000), Bergin et al. (2003), van Zadelhoff et al. (2003), and Semenov et al. (2004); for a discussion of [CAIs](#) and [chondrules](#), see the links). The viscous evolution of the disk gas is driven by the angular momentum transport due to turbulent torques. This leads to inward transport of the bulk of the disk matter ($\sim 80\%$), while a minor fraction of the disk gas carries the angular momentum outward (mostly along the midplane). This leads to a steady-state power-law surface density profile that has a radial dependence that is roughly proportional to $r^{-3/2}$ (surface density $\sim 1,700$ g cm⁻² at 1 AU for the model [solar nebula](#)). In the vertical direction, the gas density drops exponentially away from the midplane. The average temperature in disks decreases radially outward and, for a given distance, increases from the disk midplane to disk atmosphere. The stellar radiation

Protoplanetary Disk, Chemistry, Fig. 2

A sketch of the vertical structure of a protoplanetary disk

heats the upper layers such that the disk develops a flared structure. The upper disk atmosphere has a low density, resulting in higher gas temperatures compared to those of the dust. Closer to the star, the gas temperature in the disk atmosphere rises so high ($T \sim 1,000\text{--}5,000\text{ K}$) that the matter starts to evaporate. As one moves below the upper atmosphere, the disk density increases and the gas and dust temperatures reach an equilibrium value. In the very inner part, the disk midplane is again warmed up by the viscous accretion heating.

The intensity of ionizing and dissociating UV radiation is determined by the dust opacities, while penetration of the stellar X-ray radiation into the disk is controlled by the gas density structure. The larger the energy of a photon or a particle, the deeper disk regions it can reach. The stellar X-ray emitting source is often located high above the star's photosphere, at distances of several stellar radii ($\sim 0.01\text{ AU}$), and thus X-ray photons reach the disk atmosphere at an oblique angle and are able to penetrate deeper into the disk interior compared to the UV photons. The stellar UV intensity drops in the disk with radius as r^{-2} , while the X-ray intensity decreases even faster, and the interstellar UV radiation starts to prevail in the outer disk region ($r \gtrsim 100\text{ AU}$). The FUV continuum radiation is blocked by a gas column of

$< 0.01\text{ g cm}^{-2}$, hard X-ray photons ($\sim 1\text{--}5\text{ keV}$) are stopped at a gas column of $0.1\text{--}1\text{ g cm}^{-2}$, and $\sim\text{GeV}$ cosmic ray particles penetrate gas columns as large as $\sim 100\text{ g cm}^{-2}$.

Consequently, the disk structure can be divided into four chemically distinct regions: the warm “inner zone” where a planetary system is built (observable currently only at IR and optical wavelengths) and the differing layers in the outer disk region observed by modern radio-interferometric facilities. The inner region is at thermodynamical equilibrium, and chemical abundances there can be calculated as a function of temperature, pressure, and elemental abundances by ► [condensation sequence](#) modeling. The major problem here is to obtain reliable equilibrium coefficients for all species of interest. Chemical kinetics controls the evolution of the outer disk region ($r > 20\text{--}50\text{ AU}$). It is divided into a cold, dense disk midplane where dust grains are coated with ices, a slightly UV/X-ray-irradiated warm layer above the midplane with a rich chemical composition, and a heavily ionized, hot, and dilute disk atmosphere.

The key reactions for disk chemistry are summarized in Table 2. Modern astrochemical databases include up to 600 species involved in 6,000 gas-phase, gas-grain, and surface reactions. Only

Protoplanetary Disk, Chemistry, Table 2 Key chemical processes in protoplanetary disks

Name	Representation	Example	Rate ^a
Radiative association	$A + B \rightarrow AB + h\nu$	$C^+ + H_2 \rightarrow CH_2^+$	$\sim 10^{-10} - 10^{-17} \text{ cm}^3 \text{ s}^{-1}$
Ion-molecule	$A^+ + B \rightarrow C^+ + D$	$CO + H_3^+ \rightarrow HCO^+ + H_2$	$\sim 10^{-7} - 10^{-10} \text{ cm}^3 \text{ s}^{-1}$
Neutral-neutral	$A + B \rightarrow C + D$	$O + CH_3 \rightarrow H_2CO + H$	$\sim 10^{-10} - 10^{-16} \text{ cm}^3 \text{ s}^{-1}$
Charge transfer	$A^+ + B \rightarrow B^+ + C$	$C^+ + Mg \rightarrow C + Mg^+$	$\sim 10^{-9} \text{ cm}^3 \text{ s}^{-1}$
Radiative recombination	$A^+ + e^- \rightarrow A + h\nu$	$Mg^+ + e^- \rightarrow Mg + h\nu$	$\sim 10^{-12} \text{ cm}^3 \text{ s}^{-1}$
Dissociative recombination	$AB^+ + e^- \rightarrow A + B$	$HCO^+ + e^- \rightarrow CO + H$	$\sim 10^{-7} \text{ cm}^3 \text{ s}^{-1}$
Ionization	$A + h\nu \rightarrow A^+ + e^-$	$C + h\nu \rightarrow C^+ + e^-$	$\sim 10^{-10} \times RF^b \text{ cm}^3 \text{ s}^{-1}$
Dissociation	$AB + h\nu \rightarrow A + B$	$CO + h\nu \rightarrow C + O$	$\sim 10^{-10} \times RF \text{ cm}^3 \text{ s}^{-1}$
Accretion	$A + g \rightarrow A(g)$	$H_2O + g \rightarrow H_2O(g)$	$\geq 4 \cdot 10^{-6} \text{ cm}^3 \text{ s}^{-1}$
Surface reaction	$A(g) + B(g) \rightarrow AB(g)$	$H + H \rightarrow H_2$	$\geq 10^{-9} \text{ cm}^3 \text{ s}^{-1}$
Desorption	$A(g) \rightarrow A (h\nu \text{ or } T)$	$H_2CO(g) \rightarrow H_2CO$	$\sim 0 - 10^5 \text{ s}^{-1}$

^aChemical reaction rates vary widely in disks due to strong gradients of physical conditions

^bRF designates the local UV radiation field in the disk; $h\nu$ represents a photon

$\sim 10\%$ of the reaction rates have been accurately measured in the laboratory or calculated theoretically, making calculated molecular concentrations uncertain by factor of $\sim 3-5$ (see, e.g., Wakelam et al. 2006; Vasyunin et al. 2008). The most widely utilized astrochemical networks are those of the University of Manchester (UMIST) (Woodall et al. 2007), the Ohio State University (OSU) (Smith et al. 2004), Kinetic Database for Astrochemistry (KIDA; Wakelam et al. 2011), and a network incorporated in the Meudon code (Le Petit et al. 2006). Several datasets of surface reactions have also been compiled (e.g., Tielens and Hagen 1982; Hasegawa et al. 1992; Garrod and Herbst 2006).

The formation and destruction of polyatomic molecules in a **protoplanetary disk** continue from preceding dense core phase and are controlled by various chemical processes (Table 2). In the dense inner zone, three-body gas-phase processes become competitive at densities above $\sim 10^{10} - 10^{13} \text{ cm}^{-3}$ (Aikawa et al. 1999); otherwise all gas-phase reactions in PPDs are one- and two-body processes. As majority of key species such as H_2 , H_2O , and CO have been formed in cold prestellar cores or even at earlier evolutionary stages, radiative association reactions like $C^+ + H_2 \rightarrow CH_2^+$ (Herbst 1985) creating new molecular bonds are of less significance.

The reactions between neutral and charged molecules in the gas phase and on the surfaces

of dust grains dominate the synthesis of new species in disks. The ion-molecule reactions dominate the gas-phase chemistry, especially at low temperature in the outer disk region. Most of these reactions are exothermic, with high rate coefficients, $\sim 10^{-7} \text{ cm}^3 \text{ s}^{-1}$ that often increase toward low temperatures, and low (if any) reaction barriers (e.g., Dalgarno and Black 1976). The long-distance Coulomb attraction of an ion and a molecule with a high dipole moment is what makes the ion-molecule rates increase when temperature decreases. **Ion-neutral reactions** lead to the restructuring of molecular bonds. One of the most important classes of reactions in disks is proton transfer reactions involving a key H_3^+ ion, such as $H_3^+ + CO \rightarrow HCO^+ + H_2$. A number of **neutral-neutral reactions** between radicals and radicals, radicals and open-shell atoms, and radicals and unsaturated molecules are competitive in disks even at low temperatures (van Dishoeck 1988), with a typical rate coefficient that is only about an order of magnitude lower than for the ion-molecule processes (e.g., Smith et al. 2004). These reactions usually have barriers and as such become more active within the warm inner zone of a disk. One of the most interesting reactions of this type is the formation of formaldehyde: $CH_3 + O \rightarrow H_2CO + H$ (Woodall et al. 2007). The reaction rates of ion-molecule reactions are usually accurate within 50%, while

those for neutral-neutral reactions are harder to constrain due to reaction barriers.

The rapid neutralization of polyatomic molecular ions by dissociative recombination with electrons and negative ions leads to the production of smaller neutral molecules in disks. These processes are fast at low temperatures, with typical rates of about $10^{-7} \text{ cm}^3 \text{ s}^{-1}$ (Woodall et al. 2007). For nearly all observed molecules, dissociative recombination is an important formation pathway. Often, at late evolutionary phase, $\sim 0.1 \text{ Myr}$, dissociative recombination balances protonation reactions, e.g., $\text{H}_3^+ + \text{CO} \rightarrow \text{HCO}^+ + \text{H}_2$ followed by $\text{HCO}^+ + \text{e}^- \rightarrow \text{CO} + \text{H}$.

Additional energy is brought to reacting gas species by cosmic ray particles (CRPs), X-rays, and UV photons, which dissociate and ionize species, destroying molecular bonds. The cosmic rays dominate ionization at disk interiors (unless surface density does not exceed $\sim 100 \text{ g cm}^{-2}$), whereas X-rays and FUV photons are important at upper disk regions (surface density $\lesssim 1 \text{ g cm}^{-2}$). The cosmic ray- and X-ray-driven ionization is mainly caused by secondary energetic electrons upon primal ionization of H_2 . The respective reaction rates are uncertain, since the CRP and X-ray spectra cannot be directly derived from disk observations (e.g., due to local absorption of low-energy CRPs and X-rays). The key ionization reactions in PPDs are CRP/X-ray ionizations of H_2 and He.

The ionization and dissociation of some chemical species proceed by absorption of the UV continuum radiation, while other molecules are destroyed by absorbing UV photons of particular energies. For example, H_2 and CO dissociate via absorptions of FUV photons in discrete lines, whereas other molecules are dissociated either by the continuum (e.g., CH_4) or by the continuum and lines (e.g., C_2 ; see van Dishoeck et al. 2006). Atmospheres of young Sun-like stars generate nonthermal UV radiation, with an intensity at 100 AU from the star that can be as high as 1,000 (in units of the interstellar UV field, see Bergin et al. 2003). In some stars like TW Hya, a significant fraction of the total UV luminosity of the star is emitted in the $\blacktriangleright$ Ly alpha line. Stellar and interstellar UV photons are able to penetrate

deep into flaring disks by scattering on dust grains (van Zadelhoff et al. 2003). By dissociating and ionizing molecules, mild UV radiation drives active chemistry involving these ions and radicals, increasing the chemical complexity of the disk. For example, the high ratio of CN to HCN abundance observed in some disks (Dutrey et al. 1997) is attributed to the intense photodissociation of HCN when part of the stellar UV flux comes as Ly alpha photons (121.6 nm; Bergin et al. 2003).

The key photodissociation reaction in disks is that for CO – a molecule that otherwise locks up almost all the elemental carbon see (Table 2). Since the dissociation of the H_2 and CO molecules involves absorption of FUV at discrete wavelengths shortward of $\sim 115 \text{ nm}$, $\blacktriangleright$ self-shielding and isotope-selective photodissociation effects are possible. In the disks, H_2 and CO are so abundant that dissociating FUV lines saturate, shielding the rest of molecules from being destroyed (Draine and Bertoldi 1996; Lee et al. 1996). In contrast, rare, less abundant $\blacktriangleright$ isotopologs of CO absorb FUV photons at shifted wavelengths compared to $^{12}\text{C}^{16}\text{O}$, making self-shielding unimportant and enriching the gas with rare O and C isotopes (Thiemens and Heidenreich 1983).

The observed overabundance of deuterated species in disks compared to the measured interstellar D/H ratio of $\sim 10^{-5}$ is well established. Deuterium enrichment operates at low temperatures of 10–20 K via a key fractionation reaction: $\text{H}_3^+ + \text{HD} \leftrightarrow \text{H}_2\text{D}^+ + \text{H}_2 + 232 \text{ K}$ (Gerlich et al. 2002). A reactive H_2D^+ ion acts similar to H_3^+ , donating D to neutral radicals via a “protonation” reaction. For example, a predominant reaction pathway to produce DCO^+ is via the ion-molecule reaction of CO with H_2D^+ . Two other key fractionation reactions are active till higher temperatures (up to 70 K): $\text{CH}_3^+ + \text{HD} \leftrightarrow \text{CH}_2\text{D}^+ + \text{H}_2 + 390 \text{ K}$ (Asvany et al. 2004) and $\text{C}_2\text{H}_2^+ + \text{HD} \leftrightarrow \text{C}_2\text{HD}^+ + \text{H}_2 + 550 \text{ K}$. Both reactions lead to, e.g., DCN by the ion-molecule reaction, $\text{N} + \text{CH}_2\text{D}^+ \rightarrow \text{DCN}^+ + \text{H}_2$, followed by protonation reaction and then dissociative recombination. The mass-dependent fractionation for heavier elements like C and O is not that effective, due to the much lower mass difference between isotopologs, and other mechanisms, like mass-

independent isotope-selective dissociation and surface processes, have to be considered.

In cold disk regions, where $T \sim 10\text{--}120$ K, volatile species can condense out on dust grains. The rate of this freeze-out process depends on grain sizes and concentration and is effective in the outer disk midplane where grains do not grow significantly beyond $\sim 1\text{ }\mu\text{m}$. At $\sim 10\text{--}20$ K, many gas-phase molecules stick to a grain with a nearly 100% probability by [▶ weak van der Waals](#) forces, while some may form a much stronger chemical bond with the surface. Consequently, desorption of chemisorbed species requires higher temperatures/UV irradiation than that of physisorbed molecules and thus allows limited surface chemistry to occur even under harsh conditions.

Frozen species are released back to the gas by thermal evaporation, CRP heating, and UV desorption. A molecule evaporates thermally when it has energy to overcome binding to the surface (e.g., Leger et al. [1985](#)). Typical binding energies are about 1,000 K for light molecules such as CO and N₂ (Bisschop et al. [2006](#)) and larger for heavier [▶ cyanopolyynes](#) and carbon chains ($\sim 5,000$ K). CRP-induced desorption is a transient heating event when a relativistic Fe atom hits a grain and raises T to 70 K (e.g., Leger et al. [1985](#)). Also, UV photons can kick off surface molecules with a probability which has been roughly measured to be $\sim 10^{-6}\text{--}10^{-3}$ (e.g., Öberg et al. [2007](#)).

The dust grain surfaces serve as a catalyst for many reactions with slow gas-phase rates (such as endothermic reactions with barriers). The most notable example is the formation of molecular hydrogen that proceeds entirely on dust at $T < 15\text{--}20$ K (e.g., Hollenbach and Salpeter [1971](#)). A reaction may occur when an accreted atom or light radical, if it is not chemisorbed or desorbed back to the gas, hops over the surface sites and finds a radical. At low temperatures, surface hydrogenation of radicals is a key mechanism, leading to the formation of saturated products like water, methane, ammonia, and methanol (e.g., Tielens and Hagen [1982](#)). At higher temperatures of ~ 50 K, heavier reactants become mobile (such as O, C, OH, HCO, etc.), and complex

molecules are produced. So far, this is the only viable route to form complex organic matter in protoplanetary disks.

Applications

Nonexistent for this topic apart from similar fields of astronomy such as chemistry in (exo)planetary atmospheres, chemistry of primordial prebiotic molecules (in astrobiology), and isotopic fractionation in the early solar nebula.

Future Directions

The [▶ ALMA](#) interferometer in northern Chile is becoming fully operational in 2014. It will revolutionize our understanding of protoplanetary disks by providing high spatial resolution (up to $0.01''$), large collecting area ($5,000\text{ m}^2$) and thus high sensitivity, and a broad frequency coverage ($86\text{--}950$ GHz or $\sim 0.2\text{--}3$ mm). This is a gain by a factor of 50 in resolving power and orders of magnitude in sensitivity in comparison with earlier observational facilities. First, this will allow us to observe high-lying rotational transitions of simple abundant species like CO, CN, HCN, and HCO⁺ and to discover more complex molecules with weaker lines at low frequencies. With this information, we can better constrain disk chemical composition and physical conditions. Second, with much higher spatial resolution, we will be able to image planet-forming regions around nearby PPDs in detail and thus determine the distribution of and properties of dust there. Third, molecular layers in protoplanetary disks may become directly observable for the first time, allowing us to better tune theoretical disk chemical models and laboratory measurements of photodissociation and freeze-out processes. Fourth, data acquisition will be rapid with ALMA, and many protoplanetary disks around various young stars will be surveyed, enabling their proper statistical analysis. Other future instruments, like the Square Kilometer Array (SKA) at cm wavelengths, may allow the detection of low-energy lines from highly complex

(organic) species in cold disk regions. Future progress in our understanding of disk physics and chemistry will not be achieved without development of more advanced chemical disk models, in particular, including disk dynamics, grain evolution, and transport of UV and X-ray radiation. The chemical models will strongly benefit from ongoing activities of laboratory/theoretical chemists to derive the rates and products of astrophysically relevant processes, binding energies and photodesorption yields of surface species, and high-precision IR/microwave spectra of potentially detectable, chemically interesting species.

Synonyms

Pre-planetary nebulae

Definition

Protoplanetary nebulae (PPN) are objects in transition between the ► [asymptotic giant branch](#) (AGB) and the ► [planetary nebulae](#) (PN) phases of stellar evolution. The optical nebulosity of PPN is due to scattered light from the central star, not emission lines as in the case of PN. Observationally, PPN are defined as gaseous nebulae surrounding stars in a post-AGB phase of evolution showing no emission lines in their optical spectra.

History

Since the 1970s, PN have been known to be descendants of AGB stars, and the nebulae represent remnants of ejecta from AGB stars. The visual brightness of PN is the result of ► [line emission](#) from gas photoionized by a hot central star. From models of stellar evolution, it was known that the central stars of PN need a few thousand years to evolve from the end of the AGB to a temperature hot enough to emit a significant amount of ultraviolet radiation capable of photoionizing the circumstellar gas (Schönberner 1983). However, for a long time, no such transition object was known and the phase linking AGB stars and PN represented a missing link in the late stages of stellar evolution.

The emission mechanisms responsible for the brightness of PN are primarily recombination lines and collisionally excited lines. Both are extremely efficient, making PN bright optical objects (Kwok 2000). Without ionized gas, PPN have to rely on scattered light from the central stars, making the nebulosity very faint in the visible. However, since AGB stars are known to be strong infrared sources due to dust emission, it was suspected some infrared sources discovered in the Air Force Infrared Sky Survey

Protoplanetary Nebula, Fig. 1 Hubble Space Telescope Wide-Field Planetary Camera 2 image of the protoplanetary nebula IRAS 17150-3224 (the Cotton Candy Nebula). The visual brightness of the object is entirely due to scattered light. In addition to its bipolar morphology, multiple concentric arcs can also be seen

could be PPN (e.g., AFGL 618, Westbrook et al. 1975; AFGL 2688, Ney et al. 1975). After the Infrared Astronomical Satellite (IRAS) sky survey observed a large number of AGB stars and planetary nebulae, it was realized that PPN could be identified as objects having infrared colors intermediate between those of AGB stars and planetary nebulae (Volk and Kwok 1989). A systematic search of IRAS sources matching such color criteria has resulted in the discovery of ~30 PPN (Kwok 1993), one of which is shown in Fig. 1.

Overview

PPN have the following observational characteristics: (i) their central stars have spectral types intermediate between those of AGB stars and PN, usually of spectral types F, G, and K; (ii) their central stars have low surface gravity, often classified as luminosity class I or Ia; (iii) their infrared spectra are dominated by thermal continuum emission from warm dust; (iv) molecular emission lines can be seen in their

mm/submm spectra; (v) their spectral energy distributions show evidence of detached dust envelopes; and (vi) their optical nebulosity is due to scattered light.

Imaging observations by the *Hubble Space Telescope* have shown that many PPN show bipolar morphology, suggesting that the transformation from spherical to bipolar morphology has already taken place during the post-AGB phase of evolution (Balick and Frank 2002). Some PPN have binary central stars (Van Winckel 2003), which may play a role in the creation of the nebular bipolar morphology.

Most interestingly, spectral signatures of aromatic and aliphatic organics first appear during the PPN stage, suggesting that the synthesis of complex organics can occur in the circumstellar environment (Kwok et al. 1999).

Protoplasmic Theory of Life

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Definition

During the second part of the nineteenth century, the British biologist, Thomas Huxley (1825–1895), claimed that, inside the cell, the protoplasm was essentially composed of albuminoidal bodies and would be the place of the physical basis of life. This theory led some biologists, as the German Ernst Haeckel (1834–1919), to assume that origin of life could correspond to the formation of free protoplasm.

Protoplast

Ricardo Amils

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

[Spheroplast](#)

Definition

A protoplast is a bacterial, fungal, or plant cell that has had its cell wall completely or partially removed using either enzymatic or mechanical means. ► [Cell walls](#) are made of a variety of polysaccharides (► [peptidoglycan](#), chitin, cellulose). Protoplasts

are generally prepared by degrading cell walls with a mixture of appropriate polysaccharide-degrading enzymes. In the case of gram-positive ► [bacteria](#), lysozyme, an enzyme that breaks the bonds that maintain the structure of the peptidoglycan, is used. To prepare plant cell protoplasts, a mixture of hydrolyzing enzymes (cellulose, proteinase, and xylanase) is required. In the case of fungal protoplast, chitinase is the enzyme of choice. During and subsequent to digestion of the cell wall, the protoplast becomes very sensitive to osmotic stress. This means that cell wall digestion and protoplast storage must be carried out in an isotonic solution to prevent the disruption of the plasma membrane. Protoplasts are useful for genetic recombination experiments, because the absence of a cell wall facilitates the transport of DNA molecules to the cytoplasm. Protoplasts are normal cells, their growth allows the generation of cells with cell walls. Although most prokaryotes cannot survive in nature without a cell wall, some are able to do so. These include the mycoplasma, gram-positive bacteria, and *Thermoplasma*, an acidophilic and thermophilic *Euryarchaea*.

Protosolar Nebula, Minimum Mass

Avi M. Mandell
NASA Goddard Space Flight Center, Greenbelt,
MD, USA

Synonyms

[Solar nebula](#)

Definition

The minimum-mass ► [solar nebula](#) is the theoretical minimum amount of mass required to have formed the Solar System. The amount is calculated based on the known quantity of refractory elements in the planets and adjusting for the original composition of the pre-solar nebula (i.e., adjusting for the failure of most of the planets to completely incorporate the more volatile elements from the nebula). The minimum-mass solar nebula model typically assumes a surface density that decreases with orbital distance r as $r^{(-3/2)}$, with a total mass between 0.01 and 0.1 solar masses. This is comparable to the masses of some disks observed around young stars. More recent observations of disks suggest that the radial distribution of mass is flatter than the $-3/2$ power law, probably much closer to a -1 slope.

Protostars

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Keywords

Accretion · T Tauri star

Definition

Stellar evolution begins when a diffuse interstellar cloud undergoes gravitational collapse. Toward the cloud's center, a primitive star forms and continues to build up its mass from the surrounding gas. This object, called a protostar, is unique in that most of its luminosity stems from the kinetic

energy of infalling matter crashing onto its surface and surrounding disk. The infalling envelope of gas contains dust grains, which absorb and reemit stellar photons into the infrared. The fusion of deuterium inside protostars determines the location of the stellar [▶ birthline](#) in the [▶ Hertzsprung-Russell diagram](#). In the most massive protostars, ordinary hydrogen ignites while cloud infall is still occurring.

Overview

Stellar Life Cycle

All stars are born through the gravitational collapse of diffuse, interstellar clouds. During its initial, protostar phase, the star is optically invisible, as it is completely embedded in its parent cloud. Indeed, it is still gathering mass from that body. The protostar phase is unique in that the star's luminosity arises mostly from the kinetic energy of infalling gas. Following infall, the star then contracts slowly. During this longer, pre-main-sequence phase, energy is released by the increasing gravitational binding of the star.

Stars achieve maturity once they begin to fuse hydrogen into helium at their centers. This main-sequence phase comprises the longest period, by far, in the star's life. As hydrogen is consumed, the central regions of the star contract and heat up, so that successively heavier elements (helium, carbon, oxygen, etc.) begin to fuse. The process is an accelerating one. During this relatively brief post-main-sequence phase, the outer layers of the star swell, and the object brightens enormously, as a consequence of both the increased fusion and the further gravitational contraction of its central region.

The final fate of a star depends on its initial mass. Our Sun, after shedding a large amount of gas during the post-main-sequence epoch, will become a white dwarf, an object with the diameter of the Earth. Lacking nuclear reserves, the white dwarf will gradually cool over billions of years. In more massive stars, the remnant, condensed object at the center is a [▶ neutron star](#), with a diameter of a few kilometers or a [▶ black hole](#), an object so dense that not even light can escape it.

Taking a larger, galactic perspective, star formation represents the conversion of interstellar gas into the much more condensed objects we call stars. But the process does not just operate in one direction. Stars themselves spew back matter into space, in the form of winds, novae, and supernovae. This matter, enriched in heavy elements by previous fusion, cools and eventually becomes new interstellar clouds which in turn produce more stars. White dwarfs, neutron stars, and black holes constitute a sink that slowly drains mass away from this cyclical process.

Parent Clouds

The interstellar medium consists of both ionized and neutral gas. The specific interstellar clouds that form stars are those composed of molecular hydrogen and are thus known as molecular clouds. Of all the clouds in interstellar space, only these are dense and cold enough so that self-gravity plays an important role in their overall force balance. Since stars form through gravitational collapse, molecular clouds are strongly implicated in the process.

Molecular clouds have a range of sizes and masses. At the top end of the spectrum are the giant complexes. With typical sizes of 50 parsecs, these are the largest coherent entities in the Galaxy. We can also see giant molecular complexes in other, nearby spiral galaxies. All complexes are highly clumpy. A single clump can have a mass of hundreds to thousands of solar masses. The clumps are also found individually, outside of a giant complex, where they are more commonly known as dark clouds. The term refers to the fact that these objects obscure background starlight, giving the sky a patchy appearance.

Stars do not form uniformly throughout a giant complex, but only in its interior clumps. They also form within the more isolated dark clouds. But again, it is only the very densest gas that can produce stars. Both the clumps within complexes and dark clouds contain numerous patches of especially dense gas. These regions, typically 0.1 parsecs in size, are known as dense cores. They are the objects which collapse to form stars. We know this critical fact because a large fraction of dense cores contain embedded stars. The latter

appear as point sources of infrared or submillimeter radiation.

Dense cores, like their surrounding molecular gas in the clump or dark cloud, have temperatures of 10–20 K. Even this very low temperature provides some thermal pressure. Prior to its collapse, a dense core is supported against self-gravity by this outward force. The parent clump has a similarly low temperature. However, its higher mass also implies a stronger force of self-gravity. Support of the larger object comes from the pressure associated with internal, turbulent motion. Dense cores are special locations within the clump where the turbulent motion has, for some reason, died down.

Not all dense cores are currently forming stars. Barren objects called starless cores appear rather similar to those containing infrared point sources. However, the densest of the starless cores appear to be undergoing a slow, inward contraction. This motion may be the prelude to the full-scale collapse that gives rise to a star.

We know all of these facts because of the emission of radio and millimeter waves by the dense cores. The chief constituent of these objects is molecular hydrogen, which unfortunately is a very poor emitter at the extremely cold, ambient temperatures. We must therefore turn to other molecules which, despite their rarity, emit more strongly. Carbon monoxide is a convenient choice, especially for the larger clumps and dark clouds. In dense cores, the millimeter radiation from carbon monoxide becomes trapped, and other molecules must be used. Ammonia is one such species, emitting a strong spectral line at 1.3 cm.

Careful analysis of the spectral line emission, often from a variety of molecules, has yielded the densities and temperatures of all types of molecular clouds, including dense cores. Furthermore, the detailed shape of the line gives information about the gas motions. We know, for example, that larger clouds are turbulent because their carbon monoxide lines are much too broad to arise solely from thermal motion of the molecule. Conversely, it is the relative narrowness of the ammonia lines in dense cores that indicates their quiescence.

Inside-Out Collapse

It is still unclear whether we have observed dense cores in the act of collapse. As mentioned previously, a large fraction of starless cores do show signs of inward motion. The signature is an asymmetric line profile in an optically thick, i.e., relatively opaque, molecular line. The blueward component of the line is stronger than the red, and there is often a strong absorption dip near line center. Such a profile is also seen in YY Orionis stars, older, pre-main-sequence objects that are surrounded by infalling gas. In the case of dense cores, the asymmetric line is observed over a broad area and indicates slow, subsonic infall velocities. Lacking a detailed explanation for these observations, we must rely on theory to tell us how collapse proceeds.

A clear advance in our understanding of cloud collapse came in the 1960s, through computer simulations and accompanying analytical models. Prior to that time, the assumption was that clouds collapse as a whole. Moreover, collapse could lead to fragmentation and further collapse of the fragments. Theorists came to realize that this picture does not hold when the original cloud is close to a state of force balance. In that case, the density rises sharply toward the center of the object. The local [free-fall time](#) is correspondingly brief in that region. As a result, the center of the cloud collapses first, while the outer regions lag behind.

This inside-out mode of collapse undoubtedly applies to dense cores. Observations show that their internal temperatures are sufficiently high that the objects as a whole are indeed in force balance between thermal pressure and self-gravity. Moreover, the spatial rise in density toward the cloud center can be seen directly in molecular line observations. Since the strongest, highly supersonic collapse is concentrated in the central region, that motion is more difficult to observe.

Both analytic theory and numerical simulations predict that the boundary of infall spreads outward through the cloud. In effect, the collapse and infall to the central protostar has lowered the gas pressure. A rarefaction wave of collapse propagates at the local speed of sound. Given typical dense core sizes and temperatures, the wave

reaches the cloud edge in a time of 100,000 to a million years. This time span measures the lifetime of protostars.

The most detailed models assume a perfectly spherical cloud. Observations show, however, that real cores are aspherical, with aspect ratios of about 2–1. This fact alone demonstrates that there are more supporting forces than simply thermal pressure, which is intrinsically isotropic. One obvious candidate is the interstellar magnetic field, which exerts a force that is comparable to that from thermal pressure. The direction of the magnetic force depends on that of the field lines. Observers have recently begun to obtain images of bent magnetic field lines penetrating dense cores. These images were achieved by mapping the polarization direction of light emitted by dust grains. Clearly, detailing the collapse in a magnetized cloud is a more daunting proposition, and no complete models exist. Nevertheless, the general picture of inside-out collapse should hold.

What precedes collapse? To first approximation, starless cores are in a state of hydrostatic (or, more correctly, magnetostatic) equilibrium. However, the object is actually evolving. Most theorists agree that this evolution occurs through the slippage of neutral matter past the internal magnetic field, the process known as ► [ambipolar diffusion](#). This slippage is possible because it is only the charged species in the cloud (ions and electrons) that directly feel the magnetic force. These species then transfer their momentum to the neutral gas via collisions. In a dense core, however, the level of ionization is so low that such collisions are rare. Hence, gravity can pull the neutral gas inward, past the magnetic field.

While there is a good theoretical understanding of ambipolar diffusion, the applicability of the concept to dense cores is not yet secure. The difficulty is that ambipolar diffusion is relatively slow. For typical conditions, a dense core will not begin collapse for about ten million years. However, we see young clusters in which stars were born over an interval of just a few million years. Some other process, operating on a larger scale, must be synchronizing dense core contraction and collapse. One possibility is that the larger, parent body (clump or dark cloud) is also slowly

contracting and somehow stimulating the growth and collapse of its internal dense cores.

A second difficulty is that most models of collapsing, magnetized clouds find that the object flattens in a plane perpendicular to the main field direction. This finding runs counter to observations. Both starless cores and those containing central stars exhibit similar aspect ratios. One must de-project this shape to obtain the object's true, three-dimensional configuration. It appears that dense cores of both types are prolate. That is, they are elongated, rather than flattened. Clearly, there is some important ingredient missing in our understanding of the role magnetic fields play in dense core formation and collapse.

Main Accretion Phase

As the dense core collapses, the first stable object to form at its center is not a star, but a more compact cloud composed of molecular hydrogen. This short-lived entity is traditionally (and rather confusingly) known as the first core. It reaches a mass of less than 0.1 times the solar value and a radius of about 5 AU before it too collapses on itself. This second collapse is triggered by dissociation of the hydrogen molecules. Such dissociation effectively absorbs energy. Since the internal pressure is not rising appreciably during the process, gravity overwhelms it, and the first core collapses.

Following the demise of the first core, a much smaller and denser object arises at the center of infalling gas. This is a protostar. Its internal gas is ionized, and so the object will not suffer the destabilization that doomed the first core. The protostar is a genuine star, although one that is deeply buried in the infalling gas of the surrounding dense core. The period during which the dense core gas falls onto the protostar is known as the main accretion phase. As previously estimated, this phase lasts from 100,000 to a million years for a solar-type star. Figure 1 depicts schematically a protostar during its main accretion phase.

The outer boundary of an ordinary star is a photosphere, a thin surface layer through which radiation can escape. In contrast, the outer boundary of a protostar is a shock front, where infalling gas impacts the star itself. This gas is moving at

Protostars,

Fig. 1 Structure of a spherical protostar and its infalling envelope. The relative dimensions of the outer regions are greatly reduced for clarity. Note the convection induced by deuterium burning in the central protostar. Note also the conversion of optical (short-wavelength) to infrared (long-wavelength) photons in the dust envelope

hypersonic speed. Consequently, post-shock gas has a very high temperature, of order one million Kelvin. This heated gas radiates X-rays, both into the outside flow and back into the body of the protostar.

Remember that a protostar, by definition, derives most of its luminosity from infall. This luminosity is that generated just behind the accretion shock front. However, the X-ray photons themselves never leave the dense core. They are quickly absorbed by infalling gas just outside the star. This gas reradiates the energy into optical wavelengths. Thus, while the total energy output in radiation is conserved outward, the character of that radiation changes markedly.

Indeed, even the optical radiation does not escape. Infalling dust grains, present in the original dense core, absorb these photons. Heated dust grains radiate in the infrared region of the spectrum. As this infrared flux travels outward through the dust, it is continually degraded through multiple absorption and reemission to yet longer wavelengths. Eventually, the photons have such long wavelengths that they break free of the infalling, dusty gas. The dust photosphere, located some 10 AU from the central protostar, is the surface which emits the bulk of the luminosity.

The radius of the dust photosphere is still tiny compared to that of the dense core itself, which is larger by a factor of 1000. It makes sense,

therefore, that protostars are observed as unresolved point sources of infrared and submillimeter radiation inside dense cores. The energy emitted by these sources is relatively high. For a protostar of solar mass, the luminosity is about ten times the solar value, and the radiation peaks in the mid- to far-infrared regime.

The dust grains responsible for degrading the protostar's radiation into the infrared do not survive close to the central object. As they fall inward, they are heated by the outgoing flux of energy. At a distance of about 1 AU from the star, the grains reach a temperature of 1500 K and sublimate. There is thus a zone surrounding the protostar through which the shock-generated radiation can propagate freely. This region is known as the opacity gap. The inner boundary of the opacity gap is the layer of infalling gas that is absorbing the shock-generated X-rays and converting them into optical photons. The outer boundary of the gap is known as the dust destruction front.

Deuterium Fusion

Protostars, as we have emphasized, are too young and cold to fuse hydrogen into helium. Indeed, they are younger than pre-main-sequence stars, which derive their luminosity from gravitational contraction rather than fusion. Nevertheless, both protostars and pre-main-sequence stars do ignite

deuterium. This hydrogen isotope, whose nucleus consists of a proton and neutron, fuses with protons at a temperature of only 1000,000 K, an order of magnitude lower than the ignition temperature of ordinary hydrogen.

The luminosity generated by deuterium fusion represents a minor fraction of the protostar's total energy budget. Furthermore, this luminosity does not escape the star, but is absorbed in gas overlying the central region of active fusion. However, this very heating does aid in swelling the protostar as it continues gathering mass from its infalling cloud envelope. The net result is that protostars of a given mass all have nearly the same radius while burning deuterium, regardless of their detailed accretion history. This fact, in turn, means that the youngest pre-main-sequence stars have a nearly unique mass-radius relationship. These are the optically visible objects that lie along the birthline in the Hertzsprung-Russell diagram. In summary, the location of the birthline is largely determined by the phenomenon of deuterium fusion in protostars.

Deuterium fusion has another interesting consequence. The intense heat generated near the protostar's center creates thermal convection. This motion of buoyant, heated fluid elements, rather than the diffusion of photons, carries outward the protostar's luminosity. In protostars more massive than a few tenths of the solar mass, the region of convective instability extends to the surface, just below the accretion shock. This property, too, is bequeathed to the youngest pre-main-sequence stars, which are fully convective. In the present-day Sun, the convection zone extends inward from the photosphere for about the outer third of the solar radius.

Disk Formation

Our description of the main accretion phase has omitted two key ingredients – magnetic fields and rotation. We know that dense cores are penetrated by the interstellar magnetic field. If the ionization fraction in the gas is sufficiently high, this field is dragged down toward the protostar during collapse. Two circumstances prevent the buildup of very strong fields. First, field lines of opposite direction reconnect, releasing energy and

lowering the field strength. Second, in regions of very low ionization, such as those found deep inside the ► [protostellar envelope](#), the neutral matter slips past the field, in the process known as ambipolar diffusion. Since this slippage already occurred in the parent dense core prior to collapse, it must be amplified here. In any case, detailed calculations of protostellar collapse incorporating both magnetic reconnection and ambipolar diffusion are not yet available.

Rotation, the second missing ingredient, is key to the formation of circumstellar disks. Many pre-main-sequence stars are believed to have such disks. In a few cases, they have been imaged directly. In many other objects, the classical T Tauri stars, the presence of a disk is inferred from the excess emission at infrared wavelengths. It is these disk structures that ultimately form planets. Their presence in even the youngest pre-main-sequence stars implies that they were created earlier, during the protostar phase. If the collapse were spherically symmetric, no disk would arise. However, dense cores are observed to rotate, so a purely spherical picture of infall cannot be correct.

The rotation of dense cores is too slow to affect their gross structure. For example, the observed departure of these clouds from spherical symmetry cannot be attributed to rotational distortion. On the other hand, angular momentum is conserved during collapse. As each fluid element carries inward its initial angular momentum, the associated centrifugal force rises. If this force reaches or exceeds the gravity of the central protostar, the fluid element is effectively repelled. Rather than falling onto the star, it goes into orbit within the equatorial plane perpendicular to the cloud rotation axis. Thus are born circumstellar disks.

While the birth of disks is thus understood generally, our description is again a simplification. As the collapse proceeds, an increasing amount of gas is diverted to the disk, at the expense of the central star. Eventually, the mass of the disk would rival or exceed that of the protostar. But such massive disks are unstable to fragmentation. We observe intact disks, and these contain typically a few percent of the stellar mass. Some process must limit their growth. The consensus is that

matter within the disk spirals inward toward the star, a process known generically as disk accretion. The spiraling process must occur even as more matter is impacting the disk from the protostellar envelope. For many stars, the bulk of their mass may be acquired by this route, rather than by direct infall from the protostellar envelope.

What causes the spiraling? There is no generally accepted answer to this question. One widely discussed possibility is that magnetic fields become trapped in the disk and are tangled up by its rotation. In effect, the disk material becomes turbulent. As is well known in fluid dynamics, turbulence can create an effective viscosity. In principle, such internal friction causes the more rapidly orbiting disk material to transfer its angular momentum outward and to drift inward. Another possibility is that spiral arms develop in the disk, analogous to those in galaxies. Such a perturbation of the density also creates internal torques that might result in the desired effect. Yet a third possibility is that the disk sheds angular momentum in the form of a rotating, magnetized wind.

Whatever its cause, the outcome of the process is clear enough. At least half of known pre-main-sequence stars of solar-type mass, the classical T Tauri stars, are born with disks. Another portion, dubbed weak-lined stars, have little or no disk material surrounding them. Apparently, the spiraling process operated more efficiently in the latter group.

Massive Protostars

We have described how the fusion of deuterium near the center of a protostar drives convection throughout the interior. Parcels of gas, heated by the nuclear reactions, rise upward toward the surface. There, in the layers behind the accretion shock, they mix with infalling gas containing fresh deuterium. After radiating their energy, these cooler, denser parcels drift back down, to start the cycle anew. In this manner, the concentration of deuterium throughout the protostar is kept spatially uniform.

The situation changes for protostars that achieve a mass of from two to three times the

solar value. The opacity of stellar gas to radiation is a decreasing function of temperature. Since more massive protostars tend to be hotter on the inside, they are in effect more transparent to radiation. Convection ceases, first in the deep interior and then further out.

In these radiatively stable protostars, deuterium cannot be resupplied continually from the outside. Once the isotope fuses, it vanishes from the star's interior (see Fig. 2). The fuel only remains in a thin layer below the accretion shock. The fusion reactions now occur, not at the star's center, but at the bottom of this mantle. Although this mantle contains little mass and is geometrically thin, its heating has a dramatic effect. Protostars undergoing deuterium shell burning quickly swell.

These swollen protostars are the ancestors not of T Tauri stars, but of the more massive Herbig Ae and Be stars. The very youngest stars in this class indeed have observed radii that are larger than one would expect by extrapolation from their lower-mass counterparts. The theory of protostar evolution has successfully explained this fact.

Another puzzling fact is also neatly explained. Some close binary stars seem to be *twins*. That is, the masses of the two stars orbiting each other are essentially identical, to within the errors of measurement. However binary stars form in detail, it is unreasonable to expect that two dense cores (or two regions within a single dense core) would happen to produce the same stellar masses. Clearly, the two young stars must have been in contact, trading mass as they evolved. Just such a picture applies if one of the stars is swollen because of deuterium shell burning. Gas can overflow this swollen envelope and fall onto the close, companion star.

As we consider protostars with masses exceeding about ten times the solar mass, there is a new development. Interior temperatures are now so high that ordinary hydrogen, and not just the deuterium isotope, begins to fuse. The subsequent release of energy quickly overwhelms that from infall. The star essentially joins the main sequence while it is still acquiring gas from its parent dense core. Such nuclear burning protostars are the precursors to all the most massive and luminous stars

Protostars, Fig. 2 The four stages of deuterium burning in protostars. Active burning begins at the center and continues until a radiative barrier appears. The entire protostar is then stable against convection, and its interior depleted of deuterium. The fuel later ignites in a thick shell, driving convection in the outermost region

we see in our Galaxy and others, those of spectral type O and B.

In summary, O and B stars have no pre-main-sequence phase, but go directly from the protostar to the main-sequence stage of evolution. Moreover, it is not at all clear that the main accretion phase, as we have described it, applies here. The harsh ultraviolet radiation from O stars, together with their vigorous winds, tends to drive back the cloud envelope. Some researchers believe that the formation of an O star can only proceed through the coalescence of lower-mass objects. Others think that the traditional ideas concerning protostar formation continue to apply in this regime.

End of Infall

The far more common stars of solar-type mass and below do not have copious ultraviolet emission. The single biggest shortcoming in the current theory of protostars is that it gives no indication how the main accretion phase ends in general. Since the mass of the star is built up during this period, theorists cannot account for the fact that these masses have a well-documented distribution, known as the initial mass function.

Explaining the initial mass function has been a goal for many years, as yet unrealized.

In general, there are two processes that might end cloud infall. First, all of the dense core may collapse onto the star, either directly or through the circumstellar disk. This possibility was implicitly assumed in the early computer calculations of cloud collapse and protostar formation. It faces the obvious objection that there is no rigid wall separating the dense core from its surroundings. Indeed, we know little about the real transition region, beyond the fact that gas outside the dense core seems to be more turbulent than gas inside.

The second broad possibility is that the dense core is dispersed by the star itself during the infall phase. This picture gains credence from the observation that most, if not all, embedded young stars drive jets and molecular outflows. The jets are fast-moving winds expelled by the star and channeled into narrow, bipolar flows. Molecular outflows trace cloud gas that has been entrained by the jet and also driven outward in a bipolar pattern. There is no question that stellar winds do disperse molecular clouds.

A question that arises is the scale over which cloud dispersion occurs. Stellar jets extend several parsecs from their driving stars, well beyond the size of their parent dense cores. It is plausible that the larger clouds spawning entire clusters of stars are dispersed by these flows, but what of dense cores themselves? There are several images of jets erupting from seemingly intact cores. If future observations show that these clouds are more turbulent than those without internal stars, then the case for wind dispersal will be stronger.

In the last decade, several groups have documented the mass distribution of dense cores within larger molecular clouds. Dense core masses were obtained either by the observed thermal emission from heated dust grains or else by these objects' extinction of near-infrared light from background field stars. An intriguing result has emerged. The mass distribution of dense cores is very similar in shape to the initial mass function for stars. Specifically, it appears that each dense core produces, on average, a star containing about one third of the core mass.

This result, if upheld by future work, has at least two implications. First, the idea that all of dense cores collapse onto its protostar will have been disproved definitively. We are left with the wind dispersal picture. Within this context, the new results imply that each star successfully disperses its parent dense core once it reaches a fixed fraction of the core mass. Our present, admittedly limited, understanding of protostellar winds gives no clue as to why such a universal relationship should hold.

Observational Prospects

Infrared point sources are commonly seen in T associations, loose groups containing primarily T Tauri stars. The latter are optically visible objects that often have excess infrared radiation, indicating the presence of circumstellar disks. However, the very fact that they are visible means that T Tauri stars are *not* surrounded by infalling dense cores. Hence, they are in the pre-main-sequence, rather than the protostar, phase of evolution. Some of the nearby objects

that are only seen at infrared and longer wavelengths must be true protostars. Others could be pre-main-sequence stars that still possess a residual envelope of dusty gas, perhaps trapped in the star's strong magnetic field.

In principle, there is a clear distinction between these two kinds of objects. Protostars, we recall, derive most of their energy from the accretion of an infalling gaseous envelope. Pre-main-sequence stars are releasing internal energy through slow gravitational contraction, with only minor residual disk accretion. As already indicated, it has proved difficult to verify the presence of infalling motion directly. Moreover, stars of both types appear similar when cloaked in a sufficient quantity of dusty gas. Under these circumstances, the emergent spectrum largely reflects the absorption and emission properties of the dust grains and is rather insensitive to characteristics of the underlying star other than its total luminosity.

Nevertheless, there is an intriguing pattern to the spectra. For visible T Tauri stars that have an infrared excess, the observed flux declines between 2 and 10 μm . In the so-called Class I infrared sources, the flux rises in this range. Finally, there exists an even more embedded set of objects designated as Class 0. Here, there is no flux at near- or mid-infrared wavelengths. The observed emission peaks in the far infrared and continues to be strong into the submillimeter regime.

Class I sources are often loosely called "protostars." However, there is serious doubt as to whether the term applies. Relative to the pre-main-sequence phase of slow contraction, the phase of true infall is quite brief. Hence, the fraction of protostars in any T association should be correspondingly small. Class I sources, on the other hand, comprise a large fraction of the stars in the best-studied, nearby groups, typically 30% of the total membership. Moreover, a protostar should be brighter on average than a pre-main-sequence star, since it is deriving extra energy from infall. Class I sources are observed to have the same luminosities as T Tauri stars. This fact constitutes the "luminosity problem" of star formation theory.

The problem goes away if Class I sources are actually older, pre-main-sequence stars that are

still embedded in surrounding dust. Indeed, both Class I and Class 0 sources are always associated with dense cores of molecular gas. It seems that the main infall phase has ended for the former, but still might be ongoing for the latter. This supposition is supported by the lower ratio of submillimeter luminosity (tracing the envelope mass) to total luminosity in Class I sources. It is also true that Class 0 sources are brighter on average than T Tauri stars, and there are relatively few of them. This scarcity, however, hampers any attempt to draw quantitative conclusions.

It is encouraging that the dense cores surrounding both types of sources often show asymmetric profiles in molecular line emission. Such emission, we have noted, is thought to arise from inward motion of the molecular gas. The associated velocities are subsonic, far below those of gas elements entering the accretion shock of a protostar. A primary goal for the future is to obtain more direct evidence for both supersonically infalling gas and for the emission expected from the accretion shock itself.

Protostellar Envelope

Steven W. Stahler

Department of Astronomy, University of California, Berkeley, CA, USA

Definition

The mantle of gas surrounding a protostar is called the protostellar envelope. This material is freely collapsing onto the central star and its surrounding disk. The envelope is the densest portion of a ► [molecular cloud](#) core that went into gravitational collapse. Infalling, envelope material impacts the ► [protostar](#) and disk, creating a radiating shock front. The envelope gas contains solid dust grains, which absorb all optical and ultraviolet radiation from the star and accretion shock, reradiating it at infrared and longer wavelengths. Within about 1 AU from the star, the dust grains are thermally destroyed by sublimation. The dust photosphere (10 AU) is the radius at which the grains are so sparse that radiation streams passed them unimpeded. The emergent spectrum resembles a cold blackbody.

Keywords

Radial velocity · Exoplanet

Overview

Proxima b (or Proxima Centauri b) is an exoplanet orbiting the nearest star to the Sun, the star Proxima Centauri. Its discovery was reported in 2016 as the result of a specifically designed observational campaign –called Pale Red Dot – following the trail and tentative evidence accumulated over 20 years of observations with various instruments, most prominently ground-based high-precision spectrometers (Anglada-Escudé et al. 2016).

The planet was detected using the Doppler technique, which consists of measuring the radial velocity wobble caused by the counter-motion of the star with respect to the center of mass of the system. High precision instruments such as UVES, but more crucially, HARPS (both operated by the European Southern Observatory, Pepe et al. 2002) played a central role in the detection.

Proxima Centauri is a red dwarf with about 12–14% mass of the Sun. It has luminosity 500 times lower. As for red dwarfs in general, this provides several advantages towards the detection of small rocky planets in temperate orbits. The low stellar mass combined with temperate orbits close to the star which imply correspondingly larger signals. Because of the short orbital periods, the signal repeats much more often than on sun-like stars (a few weeks compared to the orbital period of one year of Earth). Thanks to these factors and with a suitable observing cadence, a detection and confirmation of Proxima b could be achieved with campaigns of a few months only (independent confirmation using ESPRESSO spectrometer by Suárez Mascareño et al. 2020).

Given that some of its characteristics are like Earth's (about 1.3–1.5 times the mass of the Earth, similar equilibrium temperature), and given this is the nearest star to us, Proxima b is considered a prime target for characterization of temperate terrestrial exoplanets, and hence for the search of evidence of life beyond the Solar System. Unfortunately, no transits have been detected, which have been searched using both space and ground-based observations (see, e.g., Jenkins et al. 2019, using the SPITZER/NASA space

telescope). Its potential for supporting Earth-like life remains unclear as for the rest of terrestrial planets around red dwarfs. The most critical unknown being the interaction and possible fate of their atmospheres as surface water reservoirs given their proximity to the star and the longer and stronger magnetic activity displayed by small stars, including recurrent megafares, and higher UV and X-ray fluxes received at the planet orbit (e.g., MacGregor et al. 2021 detection of a megafare of Proxima in multiple wavelengths). However, there is evidence that red-dwarf planets might be very volatile rich (more than a few percent of water content from start, like those of the Jovian moons, see Agol et al. 2021 for the TRAPPIST-1 System), so their evolution and suitability to support a biosphere over cosmic timescales remains unclear. The discovery of Proxima b along with other very remarkable multi-planet systems around nearby red-dwarfs (aka TRAPPIST-1, Gillon et al. 2016), combined with the imminent deployment of new major observatories (NASA's James Webb Space Telescope and the ground-based Extremely Large Telescopes) anticipates significant advancement in the search for life beyond Earth in the decades to come (2020–2030s).

Pseudofossil

Emmanuelle J. Javaux
Early Life Traces & Evolution-Astrobiology,
University of Liège, Liège, Belgium

Definition

A pseudofossil is a non-biological structure, impression, or trace resembling a biological structure. Several natural physical and chemical processes produce mineral, organic, or organo-mineral objects, traces, or patterns mimicking biological structures. Minerals or mineral-organic mixtures may auto-assemble to form complex shapes, such as spheroids aggregates, hollow tubes, or twisted, spiraling, branching tubes similar to biological shapes. Mineral precipitation or folded rocks form convex-upward layered structures resembling microbial constructions. Weathering of mineral concretions can also produce complex objects that could be mistaken as fossils. Abiotic or biological organics can migrate within rocks carried by fluids to form carbonaceous droplets or mineral casts. These structures can then be preserved three-dimensionally in chert by silicification and form

pseudofossils. Such abiotic structures differ from organic-walled microfossils that are hollow and preserved as carbonaceous compressions parallel to shale laminations. However, sub-circular grains of fossil oil (pyrobitumen) or vesicles formed by auto-assembling amphiphile lipids could be incorporated in fine-grained rocks and be mistaken for simple spheroidal fossils. Also, pebbles rolling on a soft bedding surface may leave imprints resembling biological tracks. Pseudofossils (sometimes also called “biomorphs”) can also be made artificially in the laboratory in simulated early Earth or extraterrestrial conditions.

Pseudofossils are unambiguously abiotic, in contrast to ► [dubiofossils](#). Only a multi-scale and multi-proxy combination of analyses, together with a good understanding of the physicochemical conditions of formation and of preservation of these structures (the geological context and taphonomy), and a falsification of possible abiotic hypotheses, make it possible to distinguish unambiguous fossils from pseudofossils and dubiofossils. Knowledge of non-biological processes and characterization of structures mimicking life are crucial when looking for early traces of life on Earth or for extraterrestrial life.

16 Psyche

- [Psyche](#)

Psyche

Line Drube

DLR Institute of Planetary Research,
German Aerospace Center (DLR), Berlin,
Germany

Synonyms

[16 Psyche](#)

Definition

Psyche is considered the tenth most massive main-belt asteroid and contains about 1% of all the mass in the main-belt. Its mass has been estimated based on its gravitational effect on asteroids 94 Aurora and 13,206 Baer during close flybys. Over the last 10 years, the diameter has been estimated to range from 186 to 288 km, which makes the bulk density difficult to estimate, and everything from 1.8 to 7 g/cm³ has been published.

Psyche has a featureless spectrum and a surface reflecting 12% in the visual light and an exceptionally 42% in radar, making it a metallic-rich M-type and an Xk-type. If the density turns out to be close to the 7 g/cm³, then it points toward the composition of Psyche being almost pure iron-nickel. In that case Psyche would once have been part of the metallic core of a differentiated body, which experienced a catastrophic collision, leaving the core exposed. The high metallicity makes Psyche a promising site for planetary mining companies.

Psyche orbits the Sun about three times farther out than Earth with a Psyche year being equal to 5 Earth years and a day just 4.196 h long. From radar and light-curve measurements, the shape seems to be ellipsoidal. Some postulate that Psyche might have a strong remnant magnetic field.

History

Italian astronomer Annibale de Gasparis discovered Psyche in 1852 as his fifth asteroid discovery and as the sixteenth asteroid discovered in all of history.

[Cryophile](#)

Definition

Psychrophiles (adj. psychrophilic), literally meaning cold-loving, are organisms adapted to growth at low temperatures, having an optimum growth temperature of $<15^{\circ}\text{C}$ and a maximum growth temperature of $<20^{\circ}\text{C}$. Psychrophiles are not to be confused with psychrotrophs (adj. psychrotrophic), also referred to as psychrotolerants, which are capable of growth at low temperature but grow optimally above 15°C .

History

The term “psychrophile” was first used in 1902 to refer to bacteria which could multiply at 0°C . The exact definition of a psychrophile has been disputed over time, with the definition suggested by Morita (Morita 1975) receiving general widespread acceptance. The exact parameters for classifying an organism as psychrophilic, however, are constantly under scrutiny (Feller and Gerday 2003).

Overview

Psychrophiles, also known as cryophiles, are considered to be extremophiles, flourishing in the coldest habitats on Earth and regarded as astrobiological models (Margesin and Miteva 2011). As $>80\%$ of Earth’s biosphere is permanently below 5°C (Russell et al. 1990), suitable environments for psychrophiles are widespread and include, among others, ocean waters, permafrost, glaciers, Antarctic rocks, snowfields, and polar ice caps. Although eukaryotic psychrophiles have been identified among algae (the snow algae *Chlamydomonas nivalis* being a well-studied example), yeast, fungi and protozoa, and some higher eukaryotes are considered to be psychrophilic, the prokaryotic domain (both ► [bacteria](#) and ► [archaea](#)) receives greater attention, containing the majority of known psychrophiles. Among the prokaryotes, psychrophiles are found in very diverse lineages that represent a wide variety of photosynthetic, heterotrophic, and autotrophic nutritional abilities (Scherer and Neuhaus 2006). Psychrophiles are particularly important to the ecology of permanently cold environments where they may be present in diverse bacterial assemblages. Prokaryotic psychrophiles vary in their requirement and indeed tolerance to oxygen and include (strictly) aerobic, (strictly) anaerobic, and facultative species. In addition to extremes of cold, many psychrophiles tolerate or in some cases require other extreme environmental conditions for growth and survival. Deep-sea

psychrophiles, for example, may require high pressures for growth, thus making them barophilic psychrophiles (baro-psychrophiles). Furthermore, salt-loving (halophilic) psychrophiles or halopsychrophiles have been identified inhabiting liquid brine within sea ice. Psychrophilic bacteria and archaea possess various adaptations, which allow them to thrive in cold environments (D'Amico et al. 2006; Casanueva et al. 2010). Cell integrity in many psychrophiles is maintained through increased flexibility of membranes by the inclusion of polyunsaturated fatty acids or the production of cryoprotectants such as exopolysaccharides (Méthé et al. 2005). Furthermore, cell integrity may be maintained through the production of antifreeze proteins, which protect the cells from destructive effects of ice crystals. Other psychrophile adaptations include enhanced protection against reactive oxygen species, a greater risk in cold environments due to the greater solubility of oxygen at low temperature. Psychrophile enzymes receive great industrial interest due to their high catalytic efficiency at low temperatures. Psychrophile enzymes are cold-adapted, having improved flexibility of the structural components involved in catalysis and a high specific activity at low temperatures (Feller and Gerday 1997; D'Amico et al. 2006; Scherer and Neuhaus 2006). These enzymes, however, have a low thermal stability, a factor that contributes to the heat sensitivity of psychrophiles, where exposure to even moderate temperature (e.g., room temperature) for even brief periods can result in death.

Pulsar

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

A pulsar is a rapidly rotating and strongly magnetized ► [neutron star](#) that emits a (rotating) beam of electromagnetic radiation, observable when it points toward the Earth. The gravitational collapse of the neutron star's precursor (the iron core of a massive star) produces magnetic fields of $>10^{12}$ Gauss and rotational periods of down to a few ms (as precise as an atomic clock), due to conservation of magnetic flux and angular momentum, respectively. Pulsars decelerate because of radiation losses, but accretion from a companion star may spin them up. A few pulsars are known to have planets orbiting them. While the origin of such planets is still unknown, they probably form after the supernova explosion and, in all probability, they are uninhabitable because of the intense high-energy radiation emitted by the neutron star.

Definition

Planets that orbit ► [pulsars](#) have been detected by detecting the changes in the times of the arrival of the radio pulses from the spinning host ► [neutron stars](#), which serve as ultraprecise celestial clocks.

History

At a meeting of the International Astronomical Union in Buenos Aires in 1991, Andrew G. Lyne announced the discovery of a planet orbiting the ► [pulsar](#) PSR B1829-10, based on periodic changes in the times of the arrival of pulses from the host ► [neutron star](#), measured with the radio telescope at Jodrell Bank (Bailes et al. 1991). Regrettably, the 6-month periodic signal was due to a subtle error in the treatment of the motion of the one real planet involved, namely the Earth. Nevertheless, the intense interest in PSR B1829-10 motivated theoretical work on the survival and/or formation of planets in systems involving ► [supernova](#) events, which produce pulsars. This set the stage for the dramatic discovery of a system of three planets orbiting the 6.2-millisecond (ms) pulsar PSR B1257+12,

based on observations with the giant radio telescope at Arecibo (Wolszczan and Frail 1992). The planets were soon confirmed by the detection of their mutual gravitational perturbations (Wolszczan 1994). Extensive searches for additional pulsar planets have yielded one convincing example, in the globular cluster M4. That planet orbits a close pair of stars consisting of a ► [white dwarf](#) together with the neutron star PSR B1620-26.

Overview

The discovery in 1992 and confirmation in 1994 of three planets around a neutron star, the 6.2-ms pulsar PSR B1257+12, provided the first convincing evidence for a system of exoplanets. Although these pulsar planets are definitely not hospitable to life as we know it, their very existence led to optimistic speculations about the occurrence of exoplanets in general. First, the extreme nature of the host neutron star and its evolutionary history did suggest that planets might indeed be common around various types of stars and that their diversity could not be easily foreseen from extrapolations of our knowledge of the Solar System. This view was dramatically reinforced by the celebrated discovery of the first planet around a normal star – a ► [“hot Jupiter”](#) in the surprisingly tight 4.2-day orbit around 51 Pegasi (Mayor and Queloz 1995). Second, the existence of a system of three terrestrial-mass planets around the pulsar PSR B1257+12, dynamically strikingly similar to the inner Solar System, and with a clear signature of a disk origin, supported the speculation that the frequency of occurrence of small rocky exoplanets might also be quite high. Recent evidence from surveys both for ► [radial-velocity planets](#) and for ► [transiting planets](#) is revealing that such systems are indeed common.

Basic Methodology

Observations of a newly discovered pulsar involve precise pulse timing measurements, which provide a means to model the neutron

star's rotational, astrometric, and dynamical parameters. In the case of millisecond pulsars, which are extremely stable rotators, the arrival of their clock-like pulses can be measured and predicted with an unprecedented, microsecond (μs) precision. This property has made the timing of pulsar clocks a very efficient tool to study a variety of phenomena in physics and astrophysics, including detection and characterization of their possible planet-mass companions, all the way down to masses of large asteroids.

The topocentric time-of-arrival (TOA) measurements are made at the telescope, which takes part in the Earth's rotation and in its motion within the Solar System. The TOAs are determined in terms of the local time, usually with the observatory's hydrogen maser clock. To account for the effects of the Earth's motion in an inertial reference frame and to express the TOAs in the standard units of time, the initially measured TOAs are corrected to the Terrestrial Time (TT) and then referred to the Solar System ► [barycenter](#) to give the final arrival times in units of the Barycentric Dynamical Time (TDB). Practical translation of the topocentric TOAs to the barycentric pulse arrival times is accomplished with the aid of a Solar System ► [ephemeris](#), which is used to determine the exact position and motion of the telescope at the time of observation. These data are usually extracted from the Jet Propulsion Laboratory DE200 or DE405 ephemerides. All other effects influencing the pulse arrival time, which include classical and relativistic delays in the Solar System, a dispersive delay of the signal as it propagates through the ionized ► [interstellar medium](#), and errors in the pulsar position and proper motion, are corrected for in the process of calculating the barycentric TOAs (for details, see Lorimer and Kramer 2004).

In the analysis process, the number of pulses received over a time interval between some initial epoch and the barycentric arrival time is a measure of the accumulated pulse phase. Since for most of the millisecond and binary pulsars there is no evidence that processes other than the deterministic spin down caused by a gradual loss of the neutron star's rotational energy have a significant effect on their rotational stability (this is generally

not true for young pulsars with large spin-down rates), the pulsar spin behavior can be modeled in terms of the rotation frequency and its time derivatives as a mathematical Taylor series. The parameters of the timing model are then determined as corrections to their initial values computed by means of a linearized least-square fit of the model to the pulse arrival time data.

If the pulsar has a binary companion or orbiting planets, its reflex motion translates into ► [Doppler](#) shifts of the apparent pulsar period and the equivalent, varying time delay of pulse arrival times. In the case of a single Keplerian (elliptical) orbit, the delay is modeled in terms of the five standard orbital parameters: the orbital period, the eccentricity, the argument of periastron, the projected semi-major axis, and the time of periastron passage. For a circular orbit and planet mass, m_{pl} , assumed to be much smaller than the pulsar mass, M_{psr} , the maximum TOA amplitude, Δt , can be approximated as $\Delta t \sim 0.5 a_{\text{pl}} (m_{\text{pl}}/m_{\text{Jup}}) (M_{\text{psr}}/M_{\text{Sun}})^{-1}$ where a_{pl} is the orbital radius, m_{Jup} is the mass of Jupiter, M_{Sun} is the mass of the Sun, and Δt and a_{pl} are expressed in seconds and astronomical units, respectively. An Earth-mass planet orbiting a pulsar with a typical mass of $\sim 1.35 M_{\text{Sun}}$ would generate a ~ 1 ms TOA variation, which would be easily detectable given the typical $\sim 1 \mu\text{s}$ timing precision achievable with millisecond pulsars. In principle, because of its extraordinary precision, the millisecond pulsar timing is capable of detecting large asteroids on sufficiently wide orbits.

Key Research Findings

The 6.2-ms radio pulsar, PSR B1257+12, has three terrestrial-mass planets forming a compact system that is not much larger than the orbit of Mercury (Wolszczan 1994). The relative sizes of the orbits and the distribution of masses of planets b, c, and d are strikingly similar to those of the three inner planets in the Solar System (Mazeh and Goldman 1995).

The near 3:2 ► [mean motion resonance](#) between the orbits of planets c and d in the PSR B1257+12 system and the existence of detectable gravitational

Pulsar Planets, Table 1 Observed and derived parameters for the planets orbiting PSR B1257+12 (numbers in parentheses give standard error in last displayed digit)

Semi-major axis, AU	0.19	0.36	0.46

perturbations between the two planets (Rasio et al. 1992; Wolszczan 1994) provide the mechanism to derive their masses without a priori knowledge of the orbital inclinations. A semi-analytical model, in which perturbations between the two planets are parametrized in terms of the two planetary masses and the mutual orientation of their orbits, has been applied to the PSR B1257+12 timing data by Konacki and Wolszczan (2003). A least-square fit of this model to the data yielded the true masses and orbital inclinations of planets b and c, assuming the canonical pulsar mass $M_{\text{psr}} = 1.35 M_{\text{Sun}}$. The near 3:2 mean motion resonance between planets c and d and the fact that their orbits are nearly coplanar imply that this pulsar’s planetary system has been created as the result of a disk evolution similar to that invoked to describe planet formation around normal stars (e.g., Papaloizou and Terquem 2006). Together with the true mass measurements, these results offer a fairly complete dynamical characterization of the first known exoplanetary system shown to contain terrestrial-mass planets. Its existence provides evidence that ► [protoplanetary disks](#) beyond the Sun can evolve low-mass planets to a dynamical configuration that is similar to that of the planets in the inner Solar System.

The most recent update of the parameters of the PSR B1257+12 planets has been published by Wolszczan (2008) and is summarized in Table 1. Continuing observations of the pulsar have not changed this model in any substantial way.

The early theories of the PSR B1257+12-type planet formation have been summarized by Podsiadlowski (1993) and further discussed by

Phinney and Hansen (1993). More recently, Miller and Hamilton (2001) and Hansen et al. (2009) have examined the conditions of survival and evolution of pulsar protoplanetary disks. They have concluded that an initially sufficiently massive ($>10^{28}$ g) disk would be able to resist evaporation by the pulsar accretion flux and create planets on a typical, 10^7 -year timescale. Quick formation of a sufficiently massive disk around a pulsar could, for instance, be accomplished by tidal disruption of a stellar companion (e.g., Phinney and Hansen 1993), a supernova fallback (e.g., Currie and Hansen 2007), or, possibly, in the process of a white dwarf merger (e.g., Livio et al. 1992). The possible detection of a dust disk around the X-ray pulsar, 4 U 0142+61 (Wang et al. 2006), if confirmed, may present the first direct evidence for a disk formed by the supernova fallback mechanism. These processes, although entirely feasible, cannot be very common. In fact, with the exception of PSR B1257+12, no planetary companions have emerged from precise timing observations of the known Galactic millisecond pulsars (Lorimer 2008), suggesting their rarity, independently of the specific formation mechanism.

Keywords

Adenine · Guanine · Hypoxanthine · Nitrogen heterocycle · Xanthine

Definition

A purine is an aromatic heterocyclic nitrogen compound, composed of a pyrimidine ring system fused to an imidazole ring system, with the core molecular formula $C_5H_4N_4$. Purines are weakly basic compounds. Purines are stabilized by resonance among the atoms in the ring structure, which gives most of the bonds a partial double-bond character. As a result, purines are nearly planar molecules with a slight pucker and are characterized by a strong UV absorption typically near 260 nm. Purine bases may exist in different tautomeric forms depending on the pH. At neutral pH, purines are hydrophobic and therefore relatively insoluble. Substituted purines are components of ribonucleic acids (RNA), deoxyribonucleic acids (DNA), and ► [coenzymes](#) and are broadly distributed in nature.

Overview

Purines consist of a six-membered pyrimidine ring fused to a five-membered imidazole ring. Purines (along with pyrimidines) serve as the informational monomers of RNA and DNA, the molecular carriers of genetic information. ► [Hydrogen](#) bonding and base-stacking interactions of substituted purines are important for stabilizing the three-dimensional structure of ► [nucleic acids](#). The most important biological

substituted purines are ► [adenine](#) and guanine, which are the major purine bases found in RNA and DNA. In DNA, ► [guanine](#) and adenine ► [base pair](#) (see ► [“Watson-Crick pairing”](#)) with cytosine and thymine (see ► [“Pyrimidine Base”](#)), respectively. Adenine is also found in adenosine triphosphate (see ► [“ATP”](#)) and other coenzymes. Two other important biological purines are hypoxanthine and xanthine. While hypoxanthine and xanthine are not incorporated into nucleic acids, they are important intermediates in purine metabolism.

A plausible prebiotic synthesis of adenine was first demonstrated by Oró (1960) using a mixture of ► [hydrogen cyanide](#) (HCN) and ammonia in an aqueous solution. HCN undergoes self-condensation to form diaminomaleonitrile (DAMN), a tetramer of HCN. DAMN then reacts with formamidine (formed in situ) or by photochemical rearrangement to form 4-aminoimidazole-5-carbonitrile (AICN). Finally, AICN reacts with HCN to form the purine adenine. Other purines such as guanine, hypoxanthine, and xanthine can be formed by the addition of small molecules (e.g., ► [cyanogen](#) or cyanate) to AICN or its amide, aminoimidazole carboxamide (AICA), followed by various ► [hydrolysis](#) steps. However, one drawback to this synthesis is that relatively high concentrations of HCN are required. The likelihood of such high concentrations of HCN is unclear on the early Earth especially since HCN cannot be concentrated by simple evaporation because it is more volatile than water. Miller and Orgel proposed that eutectic freezing provides a plausible concentration mechanism. In the temperature range of 0 °C to −20 °C, HCN remains in the liquid phase and can concentrate in the voids between ice crystals.

Purines (and also pyrimidines) are formed as condensation products of formamide heated at 110–160 °C in the presence of metal oxides and minerals. Under these conditions, the diversity and yield of purine synthesis can be enhanced by UV light (even in the absence of inorganic catalysts). Purines are unlikely to form and survive in most interstellar and circumstellar environments

since they are unstable against UV radiation. Purines may be able to survive if located in a dense ► [interstellar cloud](#), although no positive detection has been made yet. Purines have also been reported in carbonaceous meteorites suggesting their formation in space is possible. Martins et al. (2008) have reported that xanthine (along with the pyrimidine uracil) has an extraterrestrial origin in the Murchison meteorite based on compound-specific carbon isotopic measurements.

(PVED). Asymmetric enantiomer distribution in terrestrial biomolecules, with L-amino acids and D-sugars dominant, has been suggested to be the result of this effect. Calculations of the PVED between enantiomers of α -amino acids have suggested that the L-enantiomers are more stable than the D-enantiomers by an amount equivalent to 10^{-17} – 10^{-14} kT at room temperature. More recent calculations, however, have suggested that such conclusions may be ambiguous or erroneous, currently leaving both the direction and magnitude of the PVED an open question.

Definition

Pyrimidine is a six-membered nitrogen heterocyclic compound with the molecular formula $C_4H_4N_2$. Pyrimidine bases are weakly basic. Pyrimidines are stabilized by resonance among atoms in the ring, which gives most of the bonds a partial double-bond character. As a result, pyrimidines are planar molecules and are characterized by strong UV absorption generally near 260 nm. Pyrimidine bases may exist in different tautomeric forms depending on the pH. At neutral pH, pyrimidines are hydrophobic and therefore relatively insoluble. Substituted pyrimidines are components of ribonucleic acids (RNA),

Overview

Pyrimidines are aromatic nitrogen heterocycles with a structure similar to benzene but containing two nitrogen atoms at the 1 and 3 positions of the ring. Pyrimidines (along with purines) serve as the informational monomers of RNA and DNA, the molecular carriers of genetic information. ► [Hydrogen](#) bonding and base-stacking interactions of pyrimidines are important for stabilizing the three-dimensional structure in ► [nucleic acids](#). The most important biological substituted pyrimidines are ► [cytosine](#), ► [thymine](#), and ► [uracil](#). Cytosine and thymine are the two major pyrimidine bases in DNA and ► [base pair](#) (see ► [Watson-Crick Pairing](#)) with guanine and adenine (see ► [Purine Bases](#)), respectively. In RNA, uracil replaces thymine and base pairs with adenine.

The prebiotic synthesis of cytosine may have started with the precursor ► [cyanoacetylene](#), which is produced in spark discharge experiments of methane-nitrogen gas mixtures. The reaction of cyanoacetylene with cyanate produces cytosine. An alternative route uses cyanoacetaldehyde, which can be formed by the hydration of cyanoacetylene. Cyanoacetaldehyde reacts with urea, which is considered a common prebiotic molecule and is produced via Miller-Urey chemistry, to produce cytosine in excellent yields. Furthermore, cytosine is readily hydrolyzed to uracil. However, since cytosine is rather unstable, it raises the question if cytosine was used in the first genetic material.

A number of plausible prebiotic syntheses of uracil and thymine have been demonstrated in the laboratory. For example, uracil is liberated from ► [HCN polymers](#) upon acid hydrolysis. Schwartz and coworkers also produced uracil by UV irradiation of a mixture of urea and alanine in the presence of clay minerals. Thymine is produced via the methylation of uracil with formaldehyde and hydrazine. Thymine is also obtained from formamide in the presence of titanium dioxide heated at 160 °C.

Uracil has been identified in carbonaceous meteorites. Both pyrimidines and purines have been reported in ► [meteorites](#), which presents the tantalizing suggestion that some of the building blocks of genetic materials were delivered by meteorites (assuming these molecules do not originate from terrestrial contamination). Martins et al. (2008) have reported that uracil (along with the purine xanthine) has an extraterrestrial origin in the ► [Murchison](#) meteorite based on compound-specific carbon isotopic measurements.

Pyrite

Nicholas Arndt
Emeritus Professor, ISTerre, University Grenoble
Alpes, Grenoble, France

Synonyms

[Fool's gold](#)

Chemical Formula

FeS₂

Definition

Pyrite is an iron sulfide with the formula FeS₂. It has a metallic luster and a pale-yellow color as gold (hence the synonym “fool’s gold”). It is relatively hard and commonly forms cubic crystals. It is the most common sulfide mineral in nature and forms under a wide variety of conditions: a common accessory mineral in ► [igneous rocks](#) it segregates from magmas. It is found in ► [metamorphic rocks](#) as a product of contact metamorphism (i.e., in rocks at contact with hot magmatic bodies). It also forms as a hydrothermal mineral by precipitating from high-temperature solutions. In ► [sedimentary rocks](#), it occurs both as an authigenic mineral,

formed in the depositional environment, and as a secondary mineral, deposited during ► [diagenesis](#), i.e., the transformation of the sediment into rock. The formation of pyrite in sedimentary environments requires the presence of organic matter in the sediment (which decay contributes to a reducing environment by O₂ consumption), sulfate in the pore water, and an anaerobic environment. Pyrite figures prominently in many models in which the origin of life is related to hydrothermal vents. Pyrite formation has been for long time considered a source of energy for an autotrophic origin of life (Wächtershäuser 1988).

Pyrophosphate

Matthew A. Pasek
XUniversity of South Florida, Tampa, FL, USA

Synonyms

[Diphosphate](#)

Definition

Pyrophosphate is a dimer of orthophosphate (PO_4^{3-}), linked by a single oxygen via a dehydration reaction. Pyrophosphate hydrolyzes in water to give two molecules of orthophosphate with the release of about 20 kJ/mol at standard state. Pyrophosphate is a potential precursor to ATP as the main metabolic energy carrier of life, as it is formed by transmembrane protein proton pumping using a much simpler mechanism. Pyrophosphate may have been synthesized on the early

Earth either by dehydration reactions; by the phosphorylation of phosphate by high-energy phosphate precursors, such as reduced forms of phosphorus; or by radical-driven reactions.

Definition

Pyruvate ($\text{C}_3\text{H}_4\text{O}_3$, $\text{CH}_3\text{COCO}_2\text{H}$) is the conjugate base of pyruvic acid (2-oxopropanoic acid), the simplest keto acid. It is a key component of intermediary metabolism in all extant organisms. It is derived principally from glycolysis of glucose in many organisms and serves as a major precursor of fatty acids via the synthesis of acetyl-CoA. It is also a feedstock for the citric acid cycle in which it is carboxylated to yield oxaloacetate. It can also be shunted into amino acid metabolism by reductive amination to yield alanine and is a transient species in alcoholic fermentation, in which it is decarboxylated to yield acetaldehyde, which is ultimately reduced to yield ethanol.

Q

Q (Orbital Parameter)

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The Q parameter is one of the parameters that may be used to describe the elliptical orbit of a planet around a star; it is the distance between the star and the planet apastron (or farthest distance from the star). The parameter q , the distance between the star and an orbiting object's periastron (closest distance to the star), is traditionally used for cometary orbits in the Solar System.

Q (Tidal Quality Factor)

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

The tidal Q is a measure of a body's response to tidal distortion and is inversely proportional to the lag angle between the tidal bulge and the position of the perturbing body. For example, on a satellite orbiting close to a planet, the satellite becomes elongated as the force of gravity is stronger at the sub-planet point than on the opposite side. As the satellite orbits, this tidal bulge does not necessarily point toward the planet, due to the satellite's rotation. Rocky bodies tend to have Q-values near 100; giant planets and stars have Q-values near 10^6 . However, these numbers are very difficult to measure, and the above values are probably only accurate to about an order of magnitude. The orbital evolution of the planet-satellite (or star-planet, or star-star)

system is therefore a function of Q , with faster evolution for smaller Q -values.

Q (Toomre Parameter)

Yann Alibert¹ and Ravit Helled²

¹Space Research and Planetary Sciences, Physics Institute, University of Bern, Bern, Switzerland

²Geophysical, Atmospheric and Planetary Sciences, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel Aviv University, Tel Aviv, Israel

Keywords

Gravitational instability · Disk instability (model for giant planet formation)

Definition

In the context of planet formation the Toomre parameter Q is defined by

$$Q = c_s \Omega / \pi G \Sigma,$$

where Ω is the angular velocity, c_s is the sound speed, G is the gravitational constant, and Σ is the gas surface density of the disk.

Typically when Q is equal or smaller than one, the disk will become gravitationally unstable. Such processes in the disk can lead to the formation of gaseous planets as suggested by ► [Disk Instability, Model for Giant Planet Formation](#).

Q* (Specific Energy to Destroy an Object)

Sean N. Raymond

Laboratoire d'Astrophysique de Bordeaux, CNRS, Universite de Bordeaux, Bordeaux, France

Definition

The symbol Q^* refers to the amount of energy per unit mass needed to disrupt an object. This determines the critical collision velocity above which planetesimal collisions are erosive rather than accretionary. Stronger materials have larger values of Q^* . Values of Q^* are derived from laboratory experiments as well as from numerical simulations. The weakest objects in the Solar System (smallest values of Q^*) are thought to be a few hundred meters in size.

Quasispecies

Carlos Briones

Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Definition

A quasispecies is a distribution of ► [mutant](#) genomes centered around one dominant or master sequence. Quasispecies theory was developed by M. Eigen as a general model to understand the dynamics of the first replicative molecules in the context of the origin of information and the early evolution of life (Eigen [1971](#)). Although they were initially conceived as steady-state distributions of infinite size in equilibrium, quasispecies dynamics – characterized by a continuous process of mutant generation, competition, and selection – have also provided an interpretation of the great adaptive potential of RNA viruses (Domingo and Holland [1997](#)). Indeed, experimental evidence has shown that, due to their error-prone replication, different current biological entities behave as quasispecies: ► [viroids](#), RNA viruses, and DNA viruses that use RNA as an intermediate molecule during their replicative cycle. The response of the evolving viral quasispecies to selective pressures, e.g., immune response of the infected host or antiviral treatment, is influenced by the ensemble of mutants that compose the population (Lauring and Andino [2010](#)).

Quenching

Kensei Kobayashi

Yokohama National University, Yokohama, Japan

Definition

In chemistry and physics, quenching mainly refers to the effect of rapid cooling, though is

used in various scientific fields to denote the rapid cessation of a reaction by rapid dilution, addition of another reagent, or change of temperature. In materials science, quenching is used to give special properties to materials by heating followed by rapid cooling. In optics, quenching refers to the decrease of ► [fluorescence](#) intensity which occurs when an acceptor fluorophore is brought into close proximity of an excited donor fluorophore. When coexisting substances decrease fluorescence intensity by some processes such as a collision and a chemical reaction, the process is called chemical quenching.

In chemical evolution studies, quenching (rapid cooling) is quite important in the formation of organic compounds. Organic compounds tend to decompose when exposed to excessive amounts of energy, such as high temperatures. For example, amino acids are decomposed when they are heated at high temperature for even brief periods of time. However, when heated amino acids are quenched (quickly cooled) after heating at 250 °C for very short times, peptides can be isolated (Imai et al. [1999](#)). Another example occurs in Miller-Urey-type reactions. Gases are excited by a high-frequency electric discharge to give a plasma of atoms and molecular fragments which quickly quench once they exit the electric discharge production zone to form larger metastable species such as HCHO and HCN.

Quorum Sensing

Ricardo Amils

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

[Cell communication](#)

Definition

Quorum sensing is a type of decision-making process used by decentralized groups to coordinate behavior. Many species of bacteria use quorum sensing to coordinate their gene expression according to the local density of their population by using small diffusible molecules that pass

between neighboring cells. Cells can thus undergo communication. Similarly, some social insects use quorum sensing to make collective decisions. Some of the best-known examples of quorum sensing come from studies of bacteria. Quorum sensing can occur within a single bacterial species as well as among diverse species and can regulate a host of different processes, essentially serving as a simple communication network. Quorum sensing is a mechanism that ensures that sufficient cell numbers of a given species are present before eliciting a cell response. A variety of different molecules can be used as signals, such as lactones in Gram-negative bacteria or ► [oligopeptides](#) in Gram-positive bacteria.

R

R-Process

Nikos Prantzos
Institut d'Astrophysique de Paris, Paris, France

Definition

The r-process is one of the two main nucleosynthesis processes forming nuclei heavier than those of the iron peak, on the neutron-rich side of the nuclear stability valley. Neutron captures occur on timescales of ms, that is, short with respect to those of beta-decays (hence the r-, for *rapid*), driving the process far into the region of unstable, very neutron-rich nuclei (the “neutron-drip” line). The large neutron amounts required for the process are found either in the innermost regions of core collapse supernovae or in the collisions of neutron stars. About half of the natural nuclides heavier than iron, including the heaviest ones (thorium and uranium) are produced by the r-process.

Ross-128b

Emeline Bolmont
Observatoire de Genève, Université de Genève,
Chemin Pegasi 51, 1290, Sauverny, Switzerland

Definition

Ross-128b is a planet detected with the radial velocity technique with the HARPS spectrograph in 2018 (Bonfils et al. 2018). It has a minimal mass of 1.35 Earth mass and with its orbital period of 9.9 days, it sits close to the inner edge of the Habitable Zone of its small host star (17% the mass of our Sun).

Located at only 11 light years from our solar system, Ross-128b is one of the closest habitable zone planets (the closest being Proxima-b). However, the planet does not transit, so its atmosphere cannot be characterized using methods like transit spectroscopy (► [Planet Characterization: Transmitted Light](#)). Given its distance to our solar system, the best prospect for atmospheric characterization will come from high resolution spectroscopy at the European-Extremely Large Telescope.

Even though such observations will be challenging, Ross-128b has one advantage over Proxima-b and the TRAPPIST-1 planets: its star is much quieter. There are much less energetic radiations which could drive atmospheric escape

and desiccate the planet, or which could harm any potential life on the surface of the planet. In other words, Ross-128b might be better suited to host life than Proxima-b or the TRAPPIST-1 planets.

Radial Velocity

David W. Latham
Harvard-Smithsonian Center for Astrophysics,
Cambridge, MA, USA

Synonyms

[Doppler shift](#); [Line-of-sight velocity](#)

Definition

In astronomy, the radial velocity is the velocity of an object along the line of sight (the line connecting the observer to the object), i.e., along the radius vector to the object.

The radial velocity is usually measured using the observed ► [Doppler shift](#) of spectral lines, given by the formula $\Delta\lambda/\lambda = v/c$, where $\Delta\lambda$ is the shift in wavelength observed for the object compared to the rest wavelength, λ , and v is the velocity of the object along the line of sight. The quantity c is the speed of light (299,792 km/s). From this formula, a positive velocity away from the observer results in a shift of the wavelength to larger values. This phenomenon is often called a redshift. Similarly, a negative velocity toward the observer causes the wavelength to shift toward smaller values, resulting in a blue shift. When

the velocity is significant compared to the speed of light, a relativistic version of the formula should be used. Radial velocities of stars are normally quoted relative to the Sun (heliocentric) or relative to the center of mass of the Solar System (barycentric) when very precise velocities are needed.

Radial velocities can also be calculated from other data. For example, the changing positions of minor planets in the Solar System have been followed very accurately for many years, and the resulting orbits can be used to calculate the expected radial velocities at any time. This has allowed astronomers to check the absolute scale of their radial velocities by observing the Doppler shifts of minor planets.

- [Spectroscopic Orbit](#)

Radial-Velocity Planets

David W. Latham¹ and Nader Haghighipour²

¹Harvard-Smithsonian Center for Astrophysics, Cambridge, MA, USA

²Institute for Astronomy, University of Hawaii-Manoa, Honolulu, HI, USA

Keywords

Doppler shift · Radial velocity · Spectroscopic orbit

Definition

Radial-velocity planets are those detected indirectly by observing the orbital motion of their host stars in response to the gravitational pull of the planets. The stellar motion is measured by the ► [Doppler](#) effect on the stellar spectral lines.

History

In a system consisting of a star and a planet, because of the gravitational force of the planet on the star, the planet and its host star orbit their common center of mass. This causes variations in the distance of the star to the observer, creating what is known as radial velocity. Measuring the velocities of stars along the line of sight dates back to more than a century ago. However, it has been only in the past couple of decades that technological advancements reached to the point where the precision was good enough to detect the very small accelerations of a host star induced by orbiting planets. The first serious survey using radial velocity to search for planets around other stars was pursued by a team of Canadian astronomers in the 1980s (Campbell et al. [1988a, b](#)). The team used a hydrogen fluoride gas absorption cell to achieve a very precise wavelength calibration. Although they failed to discover any convincing evidence for planets among their modest samples of a couple dozen stars, they did successfully pioneer the absorption cell technique, which was later adopted by other groups using iodine gas. Ironically, a very tentative detection of a planet orbiting the primary star of the spectroscopic binary system γ Cephei was indeed announced by this team. However, it took another 15 years for this detection to be confirmed (Hatzes et al. [2003](#)). For more details on this discovery, see the book *Planets in Binary Stars Systems* (Haghighipour [2010](#)).

The first radial-velocity orbit for an unseen companion that could be called a giant planet (if the orbit happened to be oriented nearly edge on) was reported for star HD 114762 in 1989 (Latham et al. [1989](#)). However, the unseen companion defied conventional wisdom for being a planet on three counts. The orbital period of only 84 days placed it far inside the ► [snow line](#), where conditions would have been too hot for a ► [gas giant](#) to form; the orbit was eccentric, unlike any of the giant planets in the solar system; and the mass was at least ten times that of Jupiter, which was uncomfortably large (close to the boundary of brown dwarf regime). Thus, most astronomers

dismissed the unseen companion of HD 114762 as a star or ► [brown dwarf](#) in an orbit seen nearly face on. It was assumed that the observed orbital amplitude of 0.5 km/s was small because of the projection effects, not because the mass of the companion was small enough to be a planet.

That is how the search for planets around stars like the Sun stood until 1995, when an orbit of ► [51 Pegasi](#) was announced that implied an unseen companion with a mass half that of Jupiter and a remarkably short period of only 4.2 days (Mayor and Queloz [1995](#)). Initial resistance to accepting this discovery as a planet was soon overwhelmed by the announcement of several other low-Doppler-amplitude orbits implying ► [giant planets](#), often in eccentric orbits close to their parent stars, and some of them quite massive. At this time, a population of extrasolar planets was being revealed, although for any particular candidate, the actual mass could not be pinpointed until the inclination of the orbit to the line of sight could be established.

Ambitious Doppler surveys of hundreds and even thousands of solar-type stars rapidly

expanded the known population of radial-velocity planets. By June 2021, the total number of these planets, confirmed and with known orbital solutions, exceeded 800 (according to <https://exo.planetarchive.ipac.caltech.edu/>). As the surveys were sustained over longer durations, planets with longer periods were also discovered. As richer data sets were accumulated, systems with multiple planets were identified (there are currently almost 200 of such multiple planet systems). And, as the instrumental techniques improved, the velocity precisions improved as well and discoveries were extended to smaller masses, to the point where astronomers were able to detect planets with masses close to that of Earth's (see, for instance, the entry on "GJ 667C", ► ["Ross-128b"](#), and ► ["Proxima-b"](#)). The history of these discoveries is illustrated in Fig. 1, which plots the mass of each planet as a function of the year of discovery. In most cases, the masses are the minimum values, for orbits that happen to be viewed edge on. For those planets that transit their host stars, the ambiguity of the orbital inclination is removed, and the points give the actual masses.

Radial-Velocity Planets, Fig. 1 Diagram of radial-velocity planet masses as a function of the year of discovery. By the end of 2014, the technology had improved to the point where astronomers were able to detect planets

with masses close to that of Earth (shown as a red dashed line). In 2016, the first planet with a mass very similar to Earth's mass was detected in the habitable zone of its star: Proxima-b (Anglada-Escudé et al. [2016](#))

Basic Methodology

The most productive instruments for measuring very precise stellar radial velocities are all cross-dispersed echelle spectrometers with charge-coupled device (► [CCD](#)) detectors. For these instruments, the widths of the individual CCD pixels at the ► [spectrometer](#) focal plane correspond to a ► [Doppler shift](#) of typically 1 km/s, so to measure velocities with a precision of 1 m/s, it is necessary to determine the average position of the lines in the stellar spectrum to a precision of 1000th of a pixel or better. Planets have orbital periods that range from a fraction of a day to many years, but no spectrometer is stable at the level of 1 m/s over such time spans. Thus, it is necessary to measure and correct wavelength drifts very precisely.

Two approaches are in general used for wavelength calibration. One approach introduces a gas absorption cell into the beam of light from the telescope, usually a cell containing molecular iodine gas just before the spectrometer slit. The iodine absorption lines sample exactly the same path through the spectrometer as the stellar spectrum. Thus, any distortions in the optics or shifts in the illumination of the slit are faithfully recorded by the iodine spectrum impressed on top of the stellar spectrum. Using the iodine spectrum to correct the wavelength scale requires extensive numerical modeling in the data reduction, and separate exposures are needed of the star without iodine, to serve as a template. The other approach is to build a very stable spectrometer and to use an optical fiber to feed the stellar light into the spectrometer. If properly configured, the fiber scrambles the stellar light so that shifts due to guiding errors are reduced. Wavelength calibration is usually achieved with a thorium-argon hollow-cathode lamp, with either simultaneous calibration exposures in a separate fiber adjacent to the science fiber or sequential exposures through the science fiber before and after the science exposure. An important difference between these two approaches is the limited wavelength range of the iodine absorption spectrum, nominally in the window 500–600 nm. In contrast, the thorium-argon technique is limited

only by the stellar spectrum and the wavelength coverage of the spectrometer, which can easily span 380–900 nm.

The bulk motion of a star in orbit around the center of mass of a star-planet system is not the only possible source of Doppler shifts in the stellar spectrum. Stars with activity on their surfaces can have spots that are brought into view as the star rotates, leading to small distortions of the spectral lines and apparent Doppler shifts, and as the spot crosses from one side of the visible disk of the star to the other. Rapid rotation itself makes it difficult to measure precise radial velocities, because the rotation broadens the spectral lines and makes them shallower. Young stars tend to be active with rapid rotation, and hot stars also rotate rapidly, so they are difficult targets for the detection of radial-velocity planets. Bulk motions in the atmospheres, for example, due to convection, and global oscillations of the star can also introduce subtle shifts. Giant stars, especially the largest ones, exhibit velocity jitter due to these effects. At the other extreme, the smallest and coolest dwarf stars can also show activity, such as flares. These effects all imply that the ideal stars for large Doppler surveys for exoplanets are stars similar to the Sun, with spectral types F, G, and K.

The two most productive instruments for radial-velocity planets have been the High-Resolution Echelle Spectrometer (► [HIRES](#)) on the Keck I telescope on the summit of Mauna Kea in Hawaii and the High-Accuracy ► [Radial-Velocity](#) Planet Searcher (HARPS) on the 3.6-m ESO telescope on La Silla, Chile. HIRES uses the iodine cell approach on a general-purpose slit spectrometer, while HARPS uses thorium argon and a fiber-fed spectrometer designed to be very stable. For example, the temperature of HARPS is stabilized to a few mK, and the optics is housed inside a vacuum chamber. This eliminates the large wavelength shifts due to the changing index of refraction at the echelle grating as the ambient pressure of the local atmosphere changes. Both instruments have achieved a velocity precision for stellar observations at nominally the 1 m/s level over long time spans. This is illustrated in Fig. 2, which shows the histogram of the observed root-mean-square velocity residuals for two

Radial-Velocity Planets,

Fig. 2 Histograms of the root-mean-square velocity residuals for a sample of 143 quiet F, G, and K stars observed with HIRES and 321 quiet F, G, and K stars observed with HARPS, illustrating the quality of the data obtainable with these instruments

samples of quiet F, G, and K stars: 143 stars from the η -Earth project (Howard et al. 2010) with HIRES, and a similar but larger sample of 321 stars observed by the HARPS team. Both surveys span several years with typically at least two dozen observations per star. Recently, this fleet of instruments was joined by other spectrographs, like ESPRESSO, installed on the VLT in Paranal in Chile. ESPRESSO is now one of the most precise spectrographs available to the community. Searching for planets orbiting stars less massive than the Sun, CARMENES (Quirrenbach et al. 2016) and SPIRou are spectrographs which observe in the infrared where these stars emit more. For instance, the first CARMENES planet was a Neptune-size planet in the habitable zone of a dwarf (Reiners et al. 2018).

Key Research Findings

An orbital solution based on the spectroscopically observed radial velocities of a planet-hosting star is known as a ► [spectroscopic orbit](#). Although the orbital period and ► [eccentricity](#) can be determined unambiguously by a spectroscopic orbit,

the velocity amplitude of the orbital solution cannot, as it is not possible to determine the tilt of the orbital plane with respect to the line of sight from radial velocities alone. As a result, the velocity amplitude is only the component projected along the line of sight. That means, the true orbital amplitude and therefore the true mass of the planet (relative to the star) cannot be determined definitively. The best that can be done is to determine the minimum mass that the planet would have, if the orbit happened to be viewed edge on so that the observed velocity amplitude would be the true amplitude. Otherwise, some other techniques should be used to pin down the orbital inclination. In a few cases, astrometry has provided orbital inclinations for radial-velocity planets. However, the real breakthrough for deriving actual masses for planets came with the discovery of transiting planets; systems with orbits oriented close enough to edge on as seen from the Earth, where the planets transit across the faces of their host stars (see the entry ► [“Transiting Planets”](#)).

The amplitude of the radial velocity of a star due to the effect of its planet increases as one over the square root of the size of the orbit and one over the cube root of the orbital period. The velocity

amplitude also depends linearly on the ratio of the planet's mass to that of the star. That means, planets with large masses in short-period orbits (i.e., close to their central stars) are potentially easier to detect as they can induce larger reflex motions in the star than planets at larger distances. That has been the reason that the radial-velocity technique has been able to detect many gas giant planets similar to Jupiter in mass, in short-period orbits. Extensive Doppler surveys have shown that about 5–10% of solar-type stars are orbited by giant planets, and among these stars, those that show higher abundances of heavy elements in their atmospheres are more likely to host giant planets. The frequency of giant planets with periods longer than about 10 years is not well determined, because the surveys have not been in operation long enough yet.

One of the striking results of planet detection with radial-velocity technique is the discovery of systems with multiple planets. As suggested by theories of planet formation, planets form in

multiples. It was, therefore, expected that planetary systems around other stars would have multiple planets as well. The first multi-planet system was discovered around the star Upsilon Andromedae in 1999 (Fig. 3, Butler et al. 1999). Since then, radial velocity has been able to detect about 200 more multiple planet systems.

Another important achievement of radial-velocity surveys is the discovery of super-Earth planets (see the entry on ► “[Super-Earths](#)”), in particular around cool, low-mass stars (M dwarfs, see ► “[Spectral Type](#)”). With masses in the range of two to ten Earth masses, super-Earths may be rocky, in which case, if they orbit their host star in the Habitable Zone, they may have the potential to develop life as we know it. Around cool and low-mass stars such as M dwarfs, where the habitable zone is in a closer range (0.1–0.2 AU) compared to that around the Sun, these planets can induce large reflex motions in the star comparable with the sensitivity of radial-velocity surveys. Among the multiple

Radial-Velocity Planets, Fig. 3 The planetary system of Upsilon Andromedae, the first extrasolar multi-planet system detected (Butler et al. 1999)

planet systems discovered by radial velocity, a few have become of particular interest as they include super-Earth planets and have interesting orbital configurations. The M star Gliese 876 was the first star with two planets in a 2:1 resonance, hosting the first detected super-Earth, a 6.2-Earth-mass planet in a 2-day orbit (Marcy et al. 1998, 2001; Delfosse et al. 1998; Rivera et al. 2005). Currently, GJ 876 has four planets, including three giant planets as the only known planetary system in a 1:2:4 ▶ [Laplace resonance](#) (Fig. 4). Recently, several planets with an astrobiological interest and with masses close to that of the Earth were discovered around M dwarfs. For instance, Proxima-b (Anglada-Escudé et al. 2016) and Ross-128b (Bonfils et al. 2018). Of those two

Radial-Velocity Planets, Fig. 4 The orbits of the planets in the system of GJ 876

Radial-Velocity Planets, Fig. 5 The multi-planet system of 55 Cancri

planets, Proxima-b is by far the most promising one. Discovered around Proxima Centauri, it is the Habitable Zone planet the closest to our solar system. Its minimal mass is only 1.27 Earth mass and its atmosphere will be probed by future instruments using high-contrast and high-resolution spectroscopy (e.g., Lovis et al. 2017, see ▶ [“Planet Characterization: High-Resolution Spectroscopy”](#)).

The system of 55 Cancri is also another special multi-planet system. This system has two planets in a 1:3 resonance, one transiting super-Earth and one Jupiter analog (Fig. 5). Finally, the planetary system of Gliese 667C has also gained a great deal of attention. This system is the first planetary system with two confirmed super-Earths, one of which detected in the habitable zone.

Transiting radial-velocity planets offer the possibility of atmospheric characterization, via the disentangling of the planet from the stellar signal using a cross-correlation technique (Snellen et al. 2010). These observations allowed to detect various species in the atmospheres of ultra-hot Jupiters (e.g., Hoeijmakers et al. 2018, with the HARPS spectrograph). The advent of high-resolution spectrographs, like ESPRESSO, marked also the beginning of improvements in atmospheric characterization. Recently, using the same method, Ehrenreich et al. (2020) observed an asymmetry between the leading and trailing limb of the planet (the morning and evening limb, respectively). They interpreted it as evidence that iron condensation occurs on the night-side of the ultra-hot exoplanet WASP-76b. Although these types of observations are now only possible for hot giant planets, this is exciting

to see what high-resolution spectroscopy can achieve (see also ► [“Planet Characterization: High-Resolution Spectroscopy”](#)).

Future Directions

The orbital motion induced in a star like the Sun by a planet like the Earth in a 1-year orbit is on the order of 10 cm/s. Although it is not yet clear whether there are stars quiet enough to allow orbital motions to be detected at this level, the Echelle SPectrograph for Rocky Exoplanet and Stable Spectroscopic Observations (ESPRESSO) is a spectrometer built to be capable of 10 cm/s precision. Since 2017, this instrument is in operation on the Very Large Telescope at the European Southern Observatory in Chile. It has already contributed to interesting science and will continue for the years to come. Very soon, a new infrared spectrograph, NIRPS (seen as the “red arm” of HARPS) will be in operation at the 3.6 m telescope at La Silla Observatory in Chile. It will detect and characterize planets orbiting cool dwarfs.

Looking beyond ESPRESSO and NIRPS, a high-resolution spectrograph called HIRES (not to be confused with the High-Resolution Echelle Spectrometer on the Keck I telescope, also called HIRES) will have the potential to measure radial velocities at the level of 1 cm/s over time spans of many years. HIRES will be used with the European Extremely Large Telescope, with a start toward 2030. Note that E-ELT HIRES will also be used to characterize the atmosphere of small temperate planets around low-mass stars (such as Proxima-b, see also ► [“Planet Characterization: High-Resolution Spectroscopy”](#)).

Definition

Radiation biology is an interdisciplinary subject that describes the biological effects of ionizing radiations. It is based on studies in physics, chemistry, biology, and medicine.

History

The history of radiation biology started shortly after the discovery of X-rays in 1895 by Wilhelm Conrad Röntgen, who was awarded the first Nobel Prize in Physics in 1901. Within short time, X-rays were being used not only to take pictures of the internal organs of living people but also to treat a variety of diseases. The discovery of natural radioactivity by Antoine Henri Becquerel in 1896 was the prerequisite for the detection of terrestrial and cosmic radiation. In 1903, Becquerel shared the Nobel Prize in Physics with Pierre and Marie Curie “in recognition of the extraordinary services he has rendered by the discovery of spontaneous radioactivity.” Interaction of radiation energy with living matter was observed, and the radiation sensitivity law was formulated by Jean Alban Bergonie and Louis Tribondeau as early as 1906. The genetic effects of radiation, including the effects on cancer risk, were recognized much later. In 1946, Hermann Joseph Muller was awarded the Nobel Prize in Physiology or Medicine, for the discovery of the production of mutations by means of X-ray irradiation.

Overview

Life on Earth has been shaped by interactions of the organisms with their environment, including radiation of terrestrial and cosmic origin, by numerous adaptive responses. Radiation biology describes the interactions of radiation with living matter through primarily ionization and excitation of electrons in atoms and molecules. Starting with the energy absorption of irradiated water molecules, a series of follow-up reactions is initiated (water radiolysis) in cells and tissue which give

rise to the indirect effects of radiation in addition to the direct energy absorption effects in biological key substances, such as proteins, RNA, and DNA. Direct consequences of molecular radiation damage on cellular level are inactivation or ► [mutation](#) induction. Dependent on the organizational level of life, cellular damage may result in tissue damage or even in the death of the exposed organism. Cell killing by ionizing radiation depends on different factors, such as DNA content (target size: number and size of chromosomes) and the quality of radiation (sparsely/densely ionizing radiation). The effect of radiation on inactivation (killing) is described in terms of ► [survival](#) curves. In radiobiological terms, cell survival is understood as the ability for indefinite cell reproduction. In dose-effect curves, the surviving fraction of irradiated cells relative to that of nonirradiated cells is plotted in a half-logarithmic manner, showing the number of survivors to decrease with increasing dose. The parameter D_0 describing radiation sensitivity is derived from the slope of the terminal part of the dose-effect curve as $-1/\text{slope}$ (Fig. 1). While human cells will be killed by doses of about 1.5 Gy (D_0), yeast cells

and bacteria tolerate doses up to 50–200 Gy (D_0). The most radiation-resistant bacterium is *Deinococcus radiodurans* ($D_0 > 5000$ Gy). In response to the harmful effects of environmental radiation, life has developed a variety of defense mechanisms, including the expression of stress proteins, the activation of the immune defense, and a variety of efficient repair systems for radiation-induced DNA injury. The radiation response of each life form is influenced by the physical properties of the radiation in question. The biological effectiveness of radiation largely depends on the local energy distribution, the ► [linear energy transfer](#) (LET, measured in keV/ μm). The relative biological effectiveness (RBE) is defined as the ratio of physical doses of the densely ionizing radiation (heavy ions, neutrons) compared to the doses of sparsely ionizing standard radiation (usually 250 kV X-rays) leading to the same effect. The RBE value is different for different biological systems and end points, depending on their stage in the growth cycle and a series of environmental factors, for example, oxygen content. For interplanetary space radiation, which is composed of different radiation types and qualities, RBE values are still to be investigated.

Definition

Radiation chemistry involves chemical changes induced by ionizing radiation with energies typically above 10 eV. Ionizing radiation in cosmic chemistry includes high-energy particles (e.g., H^+ ions in cosmic rays) and high-energy photons (e.g., X-rays). Radiation chemistry of cosmic (interstellar, planetary, cometary, and satellite) ices and atmospheres leads to the extraterrestrial synthesis and destruction of prebiotic molecules. Low-energy (<20 eV) secondary electrons, the production of which is a signature characteristic of radiation chemistry, are the dominant species in condensed-phase radiation chemistry, which likely played a critical role in the extraterrestrial synthesis of prebiotic molecules in protostellar cores within dark, dense molecular clouds, facilitating molecular panspermia and possibly jump-starting life on Earth.

Overview

Extraterrestrial condensed-phase and gas-phase energetic processing to yield prebiotic molecules may occur via radiation chemistry, which is defined as the “study of the chemical changes produced by the absorption of radiation of sufficiently high energy to produce ionization” (Woods 1998). Radiation chemistry has been employed to model prebiotic chemical reaction networks (Adam et al. 2021). Ionizing radiation in extraterrestrial chemistry includes high-energy particles (e.g., MeV to TeV cosmic rays consisting mostly of protons) and high-energy photons (e.g., vacuum ultraviolet (6.2–12.4 eV), extreme ultraviolet (12.4–124 eV), X-rays (>124 eV), and γ -rays (100 keV to 1 TeV)) (Arumainayagam et al. 2019). Extraterrestrial condensed-phase radiation chemistry is thought to play an important role in the processing of (1) interstellar ices within dark, dense molecular clouds, (2) protoplanetary disk ices close to the central star (Ciaravella et al. 2020), (3) Martian subsurface environment (Atri 2020), and (4) water ice on the surface of moons such as Europa and

Enceladus. High-energy ion irradiation of cosmic ice analogs demonstrates that both synthesis (Tribbett and Loeffler 2021) and destruction (Gerakines et al. 2021) of prebiotic molecules may result from extraterrestrial condensed-phase radiation chemistry. Extraterrestrial gas-phase radiation chemistry includes gaseous molecular hydrogen ionization, leading to important interstellar processes such as proton transfer reactions followed by ion-molecule reactions (e.g., protonated methanol reacting with formaldehyde to yield methyl formate, a complex organic molecule (COM) detected in hot cores and hot corinos) (Horn et al. 2004).

Modeling radiation chemistry is extraordinarily challenging because of the associated large number of fundamental processes (Table 1).

In contrast to photochemistry, which also contributes to energetic extraterrestrial processing, radiation chemistry is characterized by four phenomena: (1) production of a cascade of low-energy (<20 eV) secondary electrons, which are thought to be the dominant driving force behind condensed-phase radiation chemistry, (2) reactions initiated by cations, (3) nonuniform distribution of reaction intermediates, and (4) nonselective chemistry leading to the production of multiple reaction products (Arumainayagam et al. 2019).

Studying Energy transfer from the ionizing radiation to the medium is key to understanding radiation chemistry (Hatano et al. 2010). Interactions of electromagnetic radiation and charged particles with matter primarily involve transferring energy to electrons and not the nuclei of the material's constituent atoms. At energies above the ionization threshold (~10 eV), photon interactions with matter occur via three processes: (1) the photoelectric effect, (2) the Compton effect, or (3) pair production (Arumainayagam et al. 2019). In contrast, protons, α particles, and heavy ions lose energy via Coulombic interactions between the ion's charge and the medium's electrons, resulting in excitations and ionizations (Arumainayagam et al. 2019). In addition to these two energy loss mechanisms, fast electrons can radiate energy by bremsstrahlung, the "braking" radiation (Arumainayagam et al. 2019).

Effects of radiation chemistry depend on the radiation type, which is determined by linear energy transfer (LET), the rate of energy deposition by an ionizing entity per unit length of track ($LET = -dE/dx$, where E is the energy of the particle and x is the distance traveled) (Arumainayagam et al. 2019). Low LET (0.2 eV/nm) gamma-ray or 1 MeV electron radiolysis of water and high LET (150 eV/nm) alpha-particle irradiation of water yield remarkably different results because the former produces isolated spurs (events hundreds of angstroms apart) (Burton 1969), while the latter produces dense tracks (events a few angstroms apart) which may allow for intraspur chemical reactions (Hatano et al. 2010). The dose-rate effect (when the results depend on not only the total energy dose but also the time required to deliver that dose) in radiation chemistry is often associated with high linear energy transfer radiation (Arumainayagam et al. 2019).

In addition to affecting the physical structure of interstellar ices via sputtering, lattice defect production, and non-thermal desorption, ionizing radiation may initiate chemical reactions in interstellar ices (Boyer et al. 2016). The dominant mechanism involves the interaction of high-energy radiation with molecules within ices, generating a cascade of low-energy electrons that can interact with the surface and bulk ice molecules (Boyer et al. 2016).

Within attoseconds, the interaction between high-energy radiation (e.g., cosmic rays) and matter produces copious numbers ($\sim 4 \times 10^4$ electrons per MeV of energy deposited) of non-thermal, secondary, low-energy (<20 eV) electrons (Arumainayagam et al. 2010). While secondary products such as excited species and ions produced from the high-energy radiation interacting with molecules cause some radiation damage, it is the secondary electron-molecule inelastic collisions that are thought to be the primary driving forces in a wide variety of radiation-induced chemical reactions (Pimblott and LaVerne 2007). Therefore, *high-energy condensed phase-radiolysis is mediated by low-energy electron-induced reactions.*

Radiation Chemistry, Table 1 Fundamental processes of radiation chemistry. (Adapted from Hatano et al. (2010) with permission from Taylor and Francis)

$AB \rightarrow AB^+ + e^-$	Direct ionization
$\rightarrow AB^{**}$	Superexcitation (direct excitation)
$\rightarrow AB^*$	Excitation (direct excitation)
$AB^{**} \rightarrow AB^+ + e^-$	Autoionization
$\rightarrow A + B$	Dissociation
$AB^+ \rightarrow A^+ + B$	Ion dissociation
$AB^+ + AB \text{ or } S \rightarrow \text{Products}$	Ion-molecule reaction
$AB^+ + e^- \rightarrow AB^*$	Electron-ion recombination
$AB^+ + S^- \rightarrow \text{Products}$	Ion-ion recombination
$e^- + S \rightarrow S^-$	Electron attachment
$e^- + nAB \rightarrow e_x^-$	Solvation
$AB^* \rightarrow A + B$	Dissociation
$\rightarrow AB$	Internal conversion and intersystem crossing
$\rightarrow BA$	Isomerization
$\rightarrow AB + h\nu$	Fluorescence
$AB^* + S \rightarrow AB + S^*$	Energy transfer
$AB^* + AB \rightarrow (AB)_2^*$	Excimer formation
$2A \rightarrow A_2$	Radical recombination
$\rightarrow C + D$	Disproportionation
$A + AB \rightarrow A_2B$	Addition
$\rightarrow A_2 + B$	Abstraction

Electron-induced dissociations proceed via one of three initial steps: electron impact ionization (typically occurring at energies above ~ 10 eV to yield an excited state cation, which may undergo ion-molecule reactions or fragment), electron impact excitation (a non-resonant process occurring at incident electron energies above

~ 3 eV), and electron attachment (to form a transient negative ion (TNI), which may undergo bond scission, a process known as dissociative electron attachment (DEA)). The electron-induced reaction yield plotted as a function of electron energy (Fig. 1) manifests maxima at specific energies (resonant scattering due to electron

Radiation Chemistry, Fig. 1 Schematic of (a) energy distribution of secondary electrons generated during a primary ionizing event (red dotted line); (b) cross-section for electron-induced dissociation for a typical molecule (blue

dashed line); (c) dissociation yield as a function of electron energy for a typical molecule (green solid line). (Reproduced from Arumainayagam et al. (2010) with permission from Elsevier)

attachment) superimposed on a smoothly increasing curve (non-resonant scattering due to electron impact ionization and/or excitation).

The production of low-energy secondary electrons during radiation chemistry may lead to reaction pathways not available to photochemistry (Arumainayagam et al. 2019). For example, while photon-induced singlet-to-triplet transitions are forbidden in the gas phase, electron-induced singlet-to-triplet transitions are allowed because the incident electron can be exchanged with those of the target molecule (Arumainayagam et al. 2010). Moreover, unlike photons, electrons can be captured into resonant negative ion states that dissociate. The resulting molecular fragments may then react with the parent molecule or other daughter products to yield products unique to electron irradiation (Arumainayagam et al. 2010). Condensed-phase extraterrestrial electron-induced reactions may predominate over photon-induced reactions because of the sheer number of

low-energy secondary electrons produced by high-energy irradiation. In contrast to photon excitation, electron excitation is not a resonant process; the incident electron transfers the fraction of its energy sufficient to excite the molecule, and any excess is removed by the scattered electron (Arumainayagam et al. 2019). This phenomenon enhances electron-induced reactions vis-à-vis photon-induced reactions (Arumainayagam et al. 2019). Reaction cross-sections can be several orders of magnitude larger for electrons than for photons, particularly at incident energies corresponding to resonances associated with dissociative electron attachment (Arumainayagam et al. 2010).

A common misconception in astrochemistry and astrobiology is that UV photons only induce photochemistry and do not initiate radiation chemistry. Reactions attributable solely to photochemistry are limited to those initiated by photons associated with far (deep)-UV (4.1–6.2 eV)

(300–200 nm), near-UV (3.1–4.1 eV) (400–300 nm), and, occasionally, visible (1.8–3.1 eV) light (Arumainayagam et al. 2019). While in photochemistry, a single low-energy (<10 eV) non-ionizing photon typically initiates one chemical reaction, in radiation chemistry, a single photon/charged particle initiates a cascade of energy-loss events such as ionization, excitation, and nuclear displacement (Arumainayagam et al. 2019). Vacuum-UV (6.2–12.4 eV) light may initiate radiation chemistry, in addition to photochemistry, because the threshold for producing secondary electrons is lower in the condensed phase than in the gas phase for a given molecule (Arumainayagam et al. 2019). Because about 40% of the flux of secondary UV photons is estimated to be ionizing (>10 eV), this UV light can produce secondary electrons and cations when interacting with interstellar ices. Therefore, secondary UV radiation and MDHL lamps typically initiate both photochemistry and radiation chemistry in cosmic ices and their analogs. While photodissociation by far-UV photons is dominated by electronic excitation (photochemistry), photodissociation by X-ray photons is mediated by ionization (radiation chemistry) (Arumainayagam et al. 2021). Therefore, photochemistry is a subset of photon-initiated chemistry. A fundamental understanding of extraterrestrial ice processing requires examining the difference in chemical effects of low-energy (<20 eV) secondary electrons (Boyer et al. 2016) – agents of radiation chemistry – and low-energy (<10 eV) photons – instigators of photochemistry.

According to a recently published book, *The Stardust Revolution*, we are in the midst of the third scientific revolution, after those of Copernicus and Darwin (Berkowitz 2012). This book espouses the astounding view that the origin of life can be traced back to the stars themselves. In 2016, unambiguous evidence for the presence of the amino acid glycine, an important prebiotic molecule, was deduced based on in situ mass-spectral studies of the coma surrounding cometary ice (Altwegg et al. 2016). This finding is significant because comets are thought to have preserved the icy grains originally found in the interstellar

medium before solar system formation. Energetic processing of cosmic ices via radiation chemistry is believed to be a dominant mechanism for the extraterrestrial synthesis of prebiotic molecules delivered to Earth via comets, asteroids, and meteorites.

Basic Methodology

Surface science techniques are typically used to analyze condensed-phase radiolysis processes relevant to astrobiology. Such experiments are usually conducted using nanoscale thin films of multilayer adsorbates under ultrahigh vacuum (UHV) conditions ($P \sim 10^{-9}$ torr). Electron-stimulated desorption (ESD) experiments, conducted *during* irradiation, have yielded vital information relevant to initial electron-induced processes. In addition, analyzing the products *following* high-energy irradiation has provided new insights into radiation chemistry. Surface science techniques such as temperature-programmed desorption (TPD), reflection absorption infrared spectroscopy (RAIRS), X-ray photoelectron spectroscopy (XPS), and high-resolution electron energy loss spectroscopy (HREELS) are particularly useful for post-irradiation analysis. The interactions of charged particles with cosmic ice analogs have been studied using multiple types of ion-beam sources, including ion implanters, van de Graaff accelerators, tandem accelerators, and cyclotrons. Synchrotron radiation sources (e.g., NSRRC in Taiwan, DESIRS beamline at SOLEIL in France) produce continuous intense photon emission capable of ionization.

Key Research Findings

1. Radiation chemistry of interstellar ices near star-forming regions likely leads to the extraterrestrial synthesis of prebiotic molecules.
2. Radiation chemistry is mediated by low-energy electrons, which may have reaction cross sections several orders of magnitude larger than those of photons.

3. Because the ionization threshold is lower in the condensed phase than in the gas phase, most “photochemistry” studies of astrochemistry likely involve radiation chemistry.

Future Directions

The newly deployed James Webb Space Telescope (JWST) should provide new insights into the mechanisms responsible (e.g., radiation chemistry) for the extraterrestrial synthesis of prebiotic molecules.

Radiation Dose

Gerda Horneck

DLR German Aerospace Center, Institute of Aerospace Medicine, Radiation Biology, Köln, Germany

Definition

Ionizing radiation is measured in the SI (International System of Units, abbreviated "SI" from the French *Le Système International d'Unités* as the modern metric system of measurement)-derived unit of absorbed dose per mass unit, the gray (Gy), with 1 Gy equal to the net absorption of 1 J in 1 kg of material (water), compared to the previously used radiation unit "rad", 1 Gy = 100 rad. The biological effectiveness of radiation largely depends on the local energy distribution in the target material, the ► [Linear Energy Transfer](#) (LET). The quality factor Q is the biological weighting function of ionizing radiation in relation to the LET of the radiation. The product of Q and the absorbed dose is the dose equivalent. The SI-derived unit for the dose equivalent is the sievert (Sv).

Radiation Pressure

Henderson James Cleaves II

Earth-Life Science Institute (ELSI), Tokyo Institute of Technology, Meguro-ku, Tokyo, Japan

Blue Marble Space Institute of Science, Washington, DC, USA

Center for Chemical Evolution, Georgia Institute of Technology, Atlanta, GA, USA

Definition

In astronomy and physics, radiation pressure is the pressure exerted upon a surface exposed to electromagnetic radiation. The pressure is the power flux density divided by the speed of light if it is absorbed. If the radiation is reflected, the radiation pressure is doubled. Radiation pressure is about 10^{-5} Pa at Earth's distance from the Sun and decreases by the square of the distance from the Sun. Though weak, such pressures produce significant effects on small particles like ions, electrons, and cometary dust particles.

Radiative Forcing

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

Radiative forcing is the difference between the radiant energy received by a planet from its sun and the energy radiated back to space. This parameter is very important for the planet's climate because positive radiative forcing will warm the planet and negative radiative forcing will cool it. There are several factors controlling the radiative forcing, such as greenhouse gases, aerosols in the atmosphere, the planetary albedo, and the ozone layer. In the early Earth, greenhouse gases, methane oozes, and albedo could have played a key role in regulating the radiative forcing and controlling ancient climates when the radiant energy from the Sun was only 70% of the present-day level (faint young Sun paradox).

Definition

The expression “radiative processes” encompasses all the various physical processes by which a medium releases energy in the form of ► [electromagnetic radiation](#). At the microscopic level, this involves the emission of a photon by an elementary particle, as the result of specific interactions with other particles or particular conditions of temperature, acceleration, and/or excitation. Several radiative processes producing ► [continuum](#) emission can be identified: on one side, blackbody and ► [bremsstrahlung radiation](#) which are the source of *thermal* emission and, on the other side, cyclotron, gyrosynchrotron, and synchrotron emission, which are linked to the spiraling of charged particles in a magnetic field and considered as *nonthermal* processes. Note that we do not consider in this entry ► [spectral line](#) emission, which results from quantum transitions between energy levels of an atom, molecule, or ion.

Overview

Since the quasi-unique source of information on celestial objects is the electromagnetic radiation they emit and which is captured by telescopes, understanding and identifying the physical processes which are at the origin of this emission are essential. Usually, the continuous emission processes that are met in astrophysics are classified into two groups: thermal and nonthermal processes. Blackbody and bremsstrahlung emissions belong to the first group. This is so because the emission is due to particles (atoms, ions, electrons) which are in thermal equilibrium, that is, whose velocities are essentially distributed according to a Maxwellian distribution.

Blackbody emission. This corresponds to the conversion into electromagnetic radiation of the heat, that is, the kinetic energy, of charged particles (electrons and protons in ordinary matter) in a material at a certain temperature. The larger the temperature, the larger the intensity of the emitted radiation, and indeed, we easily feel on our skin the thermal radiation from the Sun or from an open oven. A blackbody exhibits very well-defined thermal emission. This is a hypothetical ideal object, in thermal equilibrium at a given temperature, and that is a perfect radiator, that is,

no other object at the same temperature could emit more energy at a given wavelength. It is also a perfect absorber and thus looks black, hence its name. In the laboratory, a good approximation of a blackbody is a small hole entrance to a cavity with absorbing walls within a block (for instance, of metal), maintained at a fixed temperature.

The spectral distribution of the blackbody emission is described by the Planck law and depends only on the temperature of the object. Its main feature is to be peaked with a maximum at a wavelength given by Wien's law, approximately $\lambda(\mu\text{m}) = 3000/T(\text{K})$. On the short wavelength side, the intensity decreases very fast with an exponential behavior, while it varies in a smoother way (as a power law) at wavelengths beyond the maximum (Fig. 1).

The total power radiated by a blackbody is proportional to the fourth power of the temperature (Stefan's law).

As a first approximation, stars' and planets' emission can be described by blackbody radiation. The most perfect astrophysical blackbody is without any contest the Universe itself, which is filled with radiation peaking in the millimeter range, the cosmic microwave background (CMB); it fits Planck's law (at $T = 2.73 \text{ K}$) to within one part per thousand, as revealed by the

Radiative Processes,

Fig. 1 The spectral distribution of the blackbody emission as a function of wavelength λ for different temperatures, from 10 K (a cold dark interstellar cloud) to 10,000 K (a hot A-type star). The X and Y scales are logarithmic. One notes that the blackbody curves are nested and never cross each other. We also note the strong asymmetry between the short wavelength side where the decrease is fast (exponential) and the long wavelength side where it diminishes as λ^{-4}

satellite COBE. However, approximately black-body emission is observed in a large variety of celestial objects at very different wavelengths. To give several examples, the emission of a star as the Sun, with $T = 6000$ K, peaks at $\lambda(\mu\text{m}) = 0.5$ μm (visible); a planet like the Earth, with $T = 300$ K, emits mainly at $\lambda(\mu\text{m}) = 10$ μm (infrared); the hot gas in clusters of galaxies, with $T = 30 \times 10^6$ K, peaks at $\lambda(\mu\text{m}) = 10^{-4}$ μm , that is, in the X-ray domain. Obviously, celestial objects are not black in general; this is why an approximation called the ► **gray body** radiation is often used in models.

Bremsstrahlung. The word is German for “braking radiation.” This emission shares several characteristics with the blackbody emission, but its main feature is to be produced by a plasma of electrons and ions. Here, the emission is due to the acceleration of electrons that are deviated by electrostatic forces when they approach an ion (see Fig. 2). According to Maxwell’s equations, any charge that suffers an acceleration, in direction or in magnitude, must radiate proportionally to the square of the acceleration (Larmor’s equation).

In most cases, the plasma is made of protons and electrons (HII regions, planetary nebulae), and the derivation of the spectrum can be formulated in a rather simple way. The path of an electron is continually wiggling due to slight deviations as it passes each proton, and each wiggle produces radiation in a broad spectrum (related to the energy lost or gained in each collision). One can then consider all the cases for the minimum approach of the electron with respect to the proton and all the possible velocities for the electrons (distributed according to a Maxwell distribution) to compute the distribution of the intensity of the emission versus the frequency.

An additional complexity is introduced by the fact that the radiation is self-absorbed in the plasma, but this can be taken into account. The resulting spectrum exhibits some behaviors similar to blackbody radiation: a power law decreases at large wavelengths and an exponential one at short ones, but between those two regimes, there is no peak but rather a characteristic plateau of almost constant value on a broad range of wavelengths (Fig. 3).

Bremsstrahlung emission is seen in a variety of astrophysical plasmas: the solar corona, HII regions where it dominates over all other mechanisms in the radio domain, and the central regions of clusters of galaxies where a tenuous and very hot gas (30×10^6 K) produces an emission mainly seen in the X-ray domain.

There is another way to accelerate free particles, by considering the effects of the magnetic field. We are now facing a second family of radiative processes called nonthermal because the particles that produce them are not at local thermal equilibrium.

Gyro-emission. In a plasma, there is usually no macroscopic electric field; however, there could be a magnetic field (the plasma is then termed a magnetized plasma), and in this case, an electron of speed v will be accelerated perpendicular to its speed and to the magnetic field by the so-called Lorentz force. Again, the acceleration of the charged particle is responsible for producing radiation, but now, the movement is regular, and the electron gyrates around the direction of the magnetic field (Fig. 4). In the nonrelativistic case (low electron velocity, i.e., low temperature), the gyration is done at a fixed frequency, independent of the speed, called the gyrofrequency which depends only on magnetic field strength. The emission

Radiative Processes,

Fig. 2 An electron (red) approaching an ion (blue) deviates under the electrostatic force and then produces electromagnetic radiation because of the associated acceleration

Radiative Processes, Fig. 3 The spectrum of a plasma-emitting bremsstrahlung emission features three distinct domains (indicated on the graph) and especially a broad plateau of quasi-constant intensity. Log intensity (I_v) is plotted versus log frequency (ν)

Radiative Processes, Fig. 4 An electron spiraling in a magnetic field produces radiation as does any accelerated charged particle

from a single electron is thus uniquely determined at this frequency, giving rise to a cyclotron line at the gyrofrequency, $\nu_B = 2.8 \times 10^6 B \text{ Hz}$ (where the magnetic field B is in gauss).

At higher electron velocities (corresponding to temperatures of typically $T = 10^5\text{--}10^6 \text{ K}$), a relativistic effect appears that changes the emission pattern to a slightly asymmetric shape, and this gives rise to harmonics of the cyclotron line (so-called gyroresonance lines). Solar active regions of the corona do exhibit this type of emission.

Gyrosynchrotron emission. At mildly relativistic speeds (electron temperatures of $T = 10^9\text{--}10^{10} \text{ K}$), the asymmetric effect becomes stronger, and many harmonics appear. In parallel,

the lines become broader so that they blend together into a continuum emission. Called gyrosynchrotron emission, this type of radiation is seen in solar and stellar flares.

Synchrotron emission. When electrons reach highly relativistic speeds, the emission becomes a narrow beam in the direction of motion, including many harmonics. The resulting spectrum, after averaging over the velocity distribution of the electrons, is shifted toward high frequencies (1000 times the cyclotron frequency) and is a continuous one, whose slope is characteristic of the electrons' energy distribution. Synchrotron emission is seen in extreme energy environments such as black holes, neutron stars, and some ultra-massive black holes at the center of galaxies.

Radiative processes · Opacity · Scattering

Definition

Radiative transfer is the theory describing how electromagnetic radiation is created, transmitted, absorbed, and scattered in a medium such as a planetary atmosphere, stellar photosphere, or interstellar medium. The medium can emit, absorb, and scatter radiation with a behavior that could vary strongly with wavelength according to the different species composing the medium and their physical state.

Overview

In astrophysics, if we except the objects of the solar system visited by probes, the intrinsic properties of a celestial object must be derived from the only available information: the observed radiation. To interpret the spectrum that is emerging from the atmosphere of a planet, an interstellar cloud or from the outer layer of a star, called the photosphere, it is necessary to model not only the production of radiation at any point of the medium but also the way it is locally absorbed or scattered in any direction. The emerging radiation, which the observer will collect, is the sum of the weighted contributions of all cells within the medium.

In addition, this modeling must be done at each wavelength, since most often emission, ► [scattering](#), or absorption processes exhibit a spectral dependence, generally related to the quantum properties of the species constituting the medium; these species will have very specific signatures, for instance, absorption or emission lines. The spectral information carried by the emerging radiation is generally very rich in terms of identification of species and of their physical state (temperature, density, ionization state): this is why it is generally admitted that astrophysics was truly born with ► [spectroscopy](#). The radiative transfer theory is thus a basic tool to interpret the spectra of stars, planets, or interstellar matter and to derive properties such as composition, temperature, and density in those media.

The radiation that propagates at a given point in a medium can appear, disappear, or change, as illustrated in Fig. 1. It appears when emitted by the particles of the medium: for instance, blackbody radiation by solid tiny particles or de-excitation of an atom between two quantum states. It disappears when it undergoes absorption by the inverse mechanisms; by the way, in that case, it contributes to heating the medium and thus to increasing emission, generally at other wavelengths. It changes when it undergoes scattering (Rayleigh, Thomson, or Mie scattering, depending on which

Radiative Transfer, Fig. 1 A photon, the basic *quantum* of light, that crosses a slab in a medium can suffer three types of interaction with the particles of the medium: it can be created (*red*), be absorbed, or be scattered (*blue*)

process is dominant), which modifies its direction of propagation and sometimes its frequency.

The radiation field intensity variations, in a given direction of propagation, can be described by a differential equation containing derivatives with respect to variables of position, direction, and time: the equation of radiative transfer. Most generally, a steady state is assumed, so that the dependence upon time is not considered. Despite this simplification, the multiplicity of parameters makes it generally difficult to solve analytically the radiation transfer equation, and numerical codes must be used.

Moreover, the radiation has an influence on the matter through which it is passing, causing heating that retroactively affects radiation emission. It follows that the problem is nonlinear and must be solved iteratively in most cases. In some situations, the number of position variables can be reduced to two or one if the geometry of the system permits (e.g., spherical symmetry). Another important simplification is to assume that certain quantities do not depend on wavelength. This approximation can be difficult to justify when it comes to constructing a spectrum in wavelength; however, the approximation called the *gray case*, which consists in ignoring the variation of absorption properties of the medium with wavelength, often allows us to obtain interesting and reliable results.

Basic Methodology

The three main quantities appearing in the transfer equation are the intensity of radiation, the ► **optical depth**, and the source function.

The intensity of radiation I_ν , also called specific intensity, characterizes the energy crossing a surface in a given direction. It is defined as follows: consider radiation contained in a solid angle $d\Omega$ in a frequency interval from ν to $\nu + d\nu$, crossing an elementary area dS perpendicular to the direction of propagation (see Fig. 2). It corresponds to a flux of radiant power dP , which clearly is proportional to dS , to $d\Omega$, and to $d\nu$, so that we can write $dP = I_\nu dS d\Omega d\nu$. The intensity of radiation I_ν is thus the energy per unit area per

Radiative Transfer, Fig. 2 In a given direction, one can consider the amount of radiation that crosses a surface dS and is contained in a solid angle $d\Omega$

unit time per unit frequency per unit solid angle, crossing a surface perpendicular to the beam of radiation. If radiation propagates in vacuum without interacting with the material, its intensity remains constant.

Optical thickness (=optical depth). When the radiation passes through a medium containing particles (dust grains, molecules, neutral or ionized atoms, electrons, etc.), this material can absorb or emit luminous energy. We characterize the absorptive capability of the medium by its absorption coefficient $|\nu$ which has the dimension of the inverse of a length (and is therefore measured in m^{-1} or more usually in cm^{-1}) and is defined so as the dimensionless quantity $|\nu ds$ represents the fraction of radiation absorbed along a path of length ds . This quantity defines the optical thickness of an infinitesimal slab, $d\tau_\nu = |\nu ds$, and the absorbed intensity is $dI_\nu = I_\nu d\tau_\nu$. For a finite slab, the optical thickness is $\tau_\nu = \int_0^s |\nu ds$.

There are several advantages to using this dimensionless quantity τ_ν rather than the space variables. One is that τ represents the actual number of particles of the medium accumulated in the beam, regardless of how the density of particles varies along the beam.

Finally, one introduces the quantity ϵ_ν which characterizes the luminous energy produced

within the medium itself: ε_v is the power per unit frequency per unit volume per unit of solid angle and therefore is expressed in $\text{W cm}^{-3} \text{sr}^{-1} \text{Hz}^{-1}$. Obviously, ε_v depends on the local density of emitting particles, while one could wish to deal with a function that describes the intrinsic emission per particle: this function, called the source function S_v , is simply the ratio ε_v/κ_v . An approximation often used in astrophysics is that the source function is equal to the Planck function. This hypothesis is known as local thermodynamic equilibrium (LTE) and assumes that the different energy levels of the atoms that can emit radiation are populated as if thermodynamic equilibrium prevailed. When scattering occurs, the source function is augmented by a term which is proportional to the intensity of radiation itself.

Using those three ingredients, I_v , τ_v and S_v , one can now write the radiative transfer equation, which is nothing but the energy balance in a small slab of given thickness and surface crossed by a beam of radiation:

$$dI_v/d\tau_v = -I_v + S_v.$$

This differential equation, when integrated along the direction of a given beam, leads to:

$$I_v = I_v(0)e^{-\tau_v} + \int_0^{\tau_v} S_v(t_v)e^{-t_v} dt_v$$

where $t_v = \int_{s_1}^{s_2} \kappa_v ds$ is the optical thickness between the point s_1 and the point s_2 . The physical meaning of this formula is almost straightforward: the first term represents the intensity of the input radiation attenuated by the crossing of the medium, and the second represents the added emissions of the different elementary volumes whose contribution is weakened by absorption between the emitting point and the point where the intensity is evaluated. The simplicity of the transfer equation is, however, apparent only; for instance, one must not forget that the source function itself may depend on the intensity, implicitly when radiative heating occurs and explicitly when scattering is present, leading to a nonlinear problem.

Despite this hidden complexity, there are several classical results that can be derived in simple cases. We mention here two of the most used.

The Beer-Lambert law. If there is no emission by the medium ($S_v = 0$), then the intensity follows the simple law: $I_v = I_v(0)e^{-\tau_v}$. The exponential declines mean that the extinction can be extremely efficient as soon as τ_v becomes larger than 1. For instance, consider the center of our Galaxy, which is seen through the layer of dust particles contained in the plane of the Galaxy. If the region is only dimmed by a mere factor of 10 in the near infrared where the optical depth is about 2.5, the same layer becomes a fully opaque wall at visible wavelengths with an attenuating factor of 10^{-10} , despite the fact that the optical depth is only ten times larger.

The Barbier-Eddington approximation. Let us assume that the source function S is a linear function of the optical depth measured along the line of sight: $S(\tau) = a + b\tau$. The integral form of the transfer equation reads then:

$$\begin{aligned} I &= \int_0^\infty S(\tau)e^{-\tau} d\tau = \int_0^\infty (a + b\tau)e^{-\tau} d\tau \\ &= a + b \equiv S(\tau = 1). \end{aligned}$$

The intensity I along a line of sight is then equal to the source function at the point along this line of sight located at unit optical depth. In other words, it looks as if the medium were best summarized by the layer at optical depth 1: deeper layers are too much attenuated to be seen, and shallower ones are too tenuous to be significant contributors. It happens that even when the assumption of linearity is not valid, the Barbier-Eddington approximation still gives very good orders of magnitude estimates, and, for instance, the spectrum of planetary atmospheres is qualitatively well explained when using this relation. Conversely, the temperature profile of a planet's atmosphere can be retrieved from the infrared spectrum by an inversion scheme based for its first steps on the Barbier-Eddington approximation. The Barbier-Eddington approximation explains also why

Radiative Transfer, Fig. 3 The absorption coefficient κ_ν is maximum at the center of a spectral line and decreases in the wings. The consequence is that – at the frequency corresponding to the center of the line – the layer of the star where $\tau = 1$ is closer to the star’s surface and thus

colder (the temperature increases toward the interior of the star). The emission from this cold layer is less intense than from the deeper and thus hotter layers: the *line* appears as a dip of intensity in the spectrum (*red curve*)

Radiative Transfer, Fig. 4 If we consider a beam of radiation coming from the edge of the stellar surface, the layer where $\tau = 1$ (the distance between the *arrow heads*) on the line of sight is closer to the star’s surface (*blue layer*) and thus colder than for the beam coming from the center of the stellar disk (*the orange layer*). The edge of the disk, also called the limb, thus appears darker than the center

absorption lines are seen in the spectra of stars, as illustrated in Fig. 3.

The Barbier-Eddington relation is also used to describe qualitatively and quantitatively the limb-darkening effect, providing a fairly good agreement with observations (see Fig. 4).

Definition

Radiative Transfer is the study of the interaction between electromagnetic radiation and matter. Within planetary atmospheres, it is a major source of information (chemical composition, temperature, pressure, condensate characteristics such as density, rugosity, particle size, etc.).

Overview

General Concepts

Spectral Radiance

It is arguably the core concept of radiative transfer. $I_\nu(M, \hat{\mathbf{u}})$ represents the amount of electromagnetic power per elementary frequency $d\nu$ around a frequency ν , per elementary solid angle $d\Omega$ around the direction unit vector $\hat{\mathbf{u}}$, and per elementary surface dS around a point M orthogonal to $\hat{\mathbf{u}}$.

Depending on the unit system used for the spectral dimension, the previous definition may

swap frequency ν with wavelength λ or wavenumber $\tilde{\nu}$ instead.

$I_\nu(M, \hat{\mathbf{u}})$ can be thought as the mathematical idealization of an intuitive pencil beam of monochromatic light, and is conserved along $\hat{\mathbf{u}}$ in vacuum.

Spectral Flux Density

$I_\nu(M, \hat{\mathbf{u}})$ is an abstract quantity that cannot be directly measured. On the other hand, the derived quantity named *spectral flux density* $F_\nu(M, \hat{\mathbf{n}})$ and defined by:

$$F_\nu(M, \hat{\mathbf{n}}) = \iint_{4\pi \text{ sr}} I_\nu(M, \hat{\mathbf{u}})(\hat{\mathbf{u}} \cdot \hat{\mathbf{n}}) d\Omega(\hat{\mathbf{u}}) \quad (1)$$

can be (destructively) measured by a detector surface located in M and orthogonal to the unit vector $\hat{\mathbf{n}}$, since $F_\nu(M, \hat{\mathbf{n}})$ represents the net transport of radiative energy per unit area through the detector.

Radiative Processes

Emission occurs when energy is transferred from matter to the local radiation field.

Absorption occurs when energy is transferred from the radiation field to the local matter content.

Scattering occurs when the matter content alters the propagation of the radiative field (mainly its direction). In the usual case of *elastic* scattering, no net energy is transferred between matter and radiation, and the frequency of the scattered radiation remains unchanged.

Absorption and scattering both deplete any incident radiation beam entering a medium. For this reason, they are often grouped together under the umbrella term *extinction*.

Emission

Emission processes in planetary atmospheres fall into two main categories: *thermal* and *non-thermal*. Nonthermal processes, such as Brehmsstrahlung or airglows, usually involve charged particles found in upper atmospheres, whereas thermal emission is dominant in neutral atmospheres, which are dense enough to reach local thermodynamical equilibrium (LTE).

Blackbody

When photons and matter are fully coupled through numerous absorptions/emissions for all radiation frequencies, they adopt a common thermodynamical temperature T . The medium is then said to behave as a *blackbody*, and the radiation spectrum within obeys *Planck's law*:

$$I_\nu(M, \vec{u}) = B_\nu(T) = \frac{2h\nu^3}{c^2} \left[\exp\left(\frac{h\nu}{kT}\right) - 1 \right]^{-1} \quad (2)$$

or, using the equality $B_\lambda(T) d\lambda = B_\nu(T) d\nu$:

$$I_\lambda(M, \vec{u}) = B_\lambda(T) = \frac{2hc^2}{\lambda^5} \left[\exp\left(\frac{hc}{\lambda kT}\right) - 1 \right]^{-1} \quad (3)$$

Brightness Temperature For any frequency ν , The function $T \rightarrow B_\nu(T)$ provides a one-to-one correspondence between spectral radiance and temperature. It then follows that this function can be inverted, so that there is always a well-defined T_ν^B value such as:

$$I_\nu = B_\nu(T_\nu^B) \quad (4)$$

T_ν^B is called *brightness temperature*, and can be thought as a conversion of the spectrum I_ν in temperature (Kelvin) units. When I_ν is of thermal origin, T_ν^B is often easier to discuss and interpret (see section “[Near-Nadir Thermal Sounding](#)”).

Wien's Law $B_\lambda(T)$ exhibits an absolute maximum for a wavelength $\lambda_{\max}(T)$. It can be shown that:

$$\lambda_{\max}(T) \times T \approx 2898 \mu\text{m} \cdot \text{K} \quad (5)$$

which provides a useful way to measure the temperature of a radiating black body or good natural approximations thereof (e.g., stars).

$B_\nu(T)$ also exhibits a maximum for a frequency $\nu_{\max}$, but $\nu_{\max} \neq c/\lambda_{\max}$

Stefan-Boltzmann Law Integrating of all frequencies and computing the thermal flux emitted per blackbody surface area over a hemisphere yields:

$$\int_\nu \int_{2\pi \text{ sr}} B_\nu(T) (\hat{\mathbf{u}} \cdot \hat{\mathbf{n}}) d\Omega(\hat{\mathbf{u}}) d\nu = \sigma T^4 \quad (6)$$

where $\sigma \approx 5,670 \cdot 10^{-8} \text{ W/m}^2/\text{K}^4$ is known as the *Stefan-Boltzmann constant*.

Kirchhoff's Law of Thermal Radiation In practice, physical bodies do not behave like blackbodies. Their emitted thermal radiation can be expressed as:

$$I_\nu(T) = \varepsilon_\nu(T) B_\nu(T) \quad (7)$$

where the dimensionless $0 \leq \varepsilon_\nu(T) \leq 1$ factor is called *emissivity*. The fraction of radiation absorbed by a medium $0 \leq a_\nu \leq 1$, called *absorptance*, is equal to the emissivity according to Kirchhoff's law.

If $a_\nu(T) = \varepsilon_\nu(T)$ does not depend on ν , then the object is sometimes referred as a *gray body*. Generally speaking, the adjective *gray* is synonymous with *independent from frequency/wavelength* in a radiative transfer context.

Beer-Bougher-Lambert Law

When an incident radiation beam enters a material medium, it is progressively weakened through extinction (absorption and scattering away from its direction). This weakening can be written:

$$\frac{dI_\nu}{ds} = -k_{\text{ext},\nu} \cdot I_\nu \quad (8)$$

where s is the spatial coordinate following the beam (curvilinear abscissa). The above equation is a definition of the *extinction coefficient* $k_{\text{ext},\nu}$. Beer-Bougher-Lambert law links the beam extinction to the local matter density following:

$$k_{\text{ext},\nu} = \sigma_{\text{ext},\nu} \cdot n = \kappa_{\text{ext},\nu} \cdot \rho \quad (9)$$

n being the local number density of particles responsible for the extinction, and $\sigma_{\text{ext},\nu}$ being

the extinction *cross-section* of these particles. Alternatively, one can define the *mass extinction coefficient* $\kappa_{\text{ext},\nu}$ and use the medium mass density ρ instead. Strictly speaking, Beer-Bougher-Lambert law is valid only wherever absorbers/scatterers are diluted in an otherwise transparent medium, like a gaseous planetary atmosphere.

Optical Depth and Optical Thickness

Section “[Beer-Bougher-Lambert Law](#)” suggests that dimensionless quantity τ_ν , whose elementary variation $d\tau_\nu$ is defined as:

$$d\tau_\nu = k_{\text{ext},\nu} ds = \sigma_{\text{ext},\nu} n ds \quad (10)$$

should be used. $\tau_\nu(s)$ is known as the *optical depth* along the radiation pencil beam in the medium. Also, the related quantity:

$$\Delta\tau_\nu(s_1, s_2) = \int_{s_1}^{s_2} d\tau_\nu = \tau_\nu(s_2) - \tau_\nu(s_1) \quad (11)$$

is known as the *optical thickness* of a material slab along the beam path. The limits $\Delta\tau_\nu \ll 1$ ($\Delta\tau_\nu \gg 1$ resp.) are called *optically thin* (*thick* resp.).

Radiative Transfer Equation Without Scattering

Formulation

Substituting τ_ν for s in Eq. (8) directly yields:

$$\frac{dI_\nu}{d\tau_\nu} = -I_\nu \quad (12)$$

valid for I_ν when no radiation source at frequency ν exists in the medium. Otherwise, a more general radiative transfer equation can be formulated:

$$\frac{dI_\nu}{d\tau_\nu} = -I_\nu + S_\nu \quad (13)$$

where S_ν is known as the *source term*. Neglecting scattering, and when LTE at a temperature T is reached, then it can be shown that $S_\nu = B_\nu(T)$.

Formal Solution

Equation (13) can be integrated along the beam path, between, for example, $\tau_\nu = 0$ and $\tau_\nu = \tau^*$, yielding:

$$I_\nu(\tau^*) = I_\nu(0)e^{-\tau^*} + \int_{\tau'=0}^{\tau^*} S_\nu(\tau')e^{\tau^*-\tau'} d\tau' \quad (14)$$

whose interpretation is straightforward: the intensity at the exit of the pencil beam is the sum of two contributions, first the incoming intensity attenuated by the optical thickness of the whole medium, and second the contribution of all sources along the pencil beam, each attenuated according to the remaining optical thickness.

Equation (14) is valid only when S_ν is independent from the existing radiation field I_ν . This is the case at LTE when scattering can be neglected.

Absorption and Spectroscopy

Beer-Bougher-Lambert law does not deal with the variations of σ_ν (or equivalently κ_ν) with respect to ν , which is the central topic of *spectroscopy*. For extinction caused by condensed matter (e.g., aerosols in planetary atmospheres), these spectral variations are usually smooth and well understood if particle shapes, sizes, and complex refractive index are known (see section “[Scattering](#)”). Gaseous absorption is usually ascribed to whether line or continuum opacities.

Line Frequencies

A line is defined as a spectrally sharp opacity feature centered on a frequency ν_0 . This central frequency is directly related to the difference in energy between initial and final quantum states of the gas molecules: $h\nu_0 = hc\tilde{\nu}_0 = |E_{\text{[final]}} - E_{\text{[initial]}}|$. Spectral lines in gases are therefore associated with *transitions* between quantum states, and are usually classified into three categories:

Electronic Transitions between molecular electronic orbitals. Typical transition energy is a few eV, yielding photons in the visible/UV range.

Vibrational Transitions between quantum states of molecular bonds stretching. Typical transition energy is less than 0.1 eV, yielding photons in the infrared range.

Rotational Transitions between quantum states of molecular rotation. Typical transition energy is below 1 meV, yielding photons in the microwave range.

Moreover, rotational and vibrational levels are usually coupled according to *quantum selection rules*, creating *rovibrational* line systems grouped in two (or three) *branches*:

P-branch $\nu < \nu_c$ where ν_c is the frequency associated with the pure vibrational transition (no change in rotational levels).

Q-branch $\nu \approx \nu_c$. Not always present, depending on quantum selection rules for the molecules.

R-branch $\nu > \nu_c$.

Line Shapes

Spectral lines are not purely monochromatic. In planetary atmospheres, two main phenomena contribute to broadening them to neighboring frequencies.

Doppler broadening: Individual molecular lines are blue/red shifted due to their random thermal speed with respect to the observer. Results in a *Gaussian* broadening, with $\Delta\nu/\nu \propto \sqrt{T}$.

Collisional broadening: Loss of phase coherence according to the typical mean free path lifetime occurs due to collisions between molecules. Results in a *Lorentzian* broadening, with $\Delta\nu/\nu \propto P/\sqrt{T}$.

Doppler broadening dominates in high- T , low- P conditions typically found in upper atmospheres. Elsewhere, both kinds of broadening are of similar strength and must be taken into account together. This yields the so-called *Voigt profile* resulting from the convolution of the Gaussian and the Lorentzian line shape functions. However, the validity of Voigt profiles degrades quite quickly far away from the central frequency,

with most gases being somewhat less opaque than the Voigt profile would predict (*sub-Lorentzian* behavior).

Continuum Opacity

Even at frequencies far from spectral lines centers, dense and relatively cold gases exhibit some opacity, labeled *collision-induced absorption* (CIA). The underlying mechanisms are multiple and notoriously hard to model: summation of multiple wings from far-away spectral lines, formation of short-lived dimers during molecular collisions, with their own transient energy levels and line systems, mutual polarizations of otherwise non-polarized molecules, opening new “forbidden” lines, etc.

The final result is a spectrally smooth opacity occurring in all dense enough planetary atmospheres (typically a few bars or more), decreasing with T and ν , and proportional to P^2 (rather than P like spectral line opacities). They are named by listing involved molecular or atomic species (two or three at most): for example, H_2-H_2 , H_2-He , H_2O-CO_2 . One can note that even gaseous species without significant line absorption (such as noble gases or diatomic homonuclear molecules like N_2 and O_2) can and do contribute to the continuum opacity.

Scattering

Single Scattering Albedo ϖ_0

It is a dimensionless quantity which expresses the relative importance of absorption and scattering in local extinction. Defining k_{abs} and k_{sca} the local absorption (scattering resp.) coefficients, ϖ_0 is defined by:

$$\varpi_0 = \frac{k_{\text{sca}}}{k_{\text{sca}} + k_{\text{abs}}} \quad (15)$$

with previously (Eq. 8) defined $k_{\text{ext}} = k_{\text{sca}} + k_{\text{abs}}$. Therefore, $0 \leq \varpi_0 \leq 1$, with $\varpi_0 = 0$ implying no scattering as previously considered. For clarity's sake, the spectral index ν was omitted, although ϖ_0 depends on ν , usually increasing with increasing ν .

Phase Function P

It describes the angular distribution of scattered radiation, depending on both incoming $\hat{\mathbf{u}}$ and outgoing $\hat{\mathbf{v}}$ directions. More specifically,

$$dp(\hat{\mathbf{u}}, \hat{\mathbf{v}}) = P(\hat{\mathbf{u}}, \hat{\mathbf{v}}) \frac{d\Omega(\hat{\mathbf{v}})}{4\pi \text{ sr}} \quad (16)$$

where dp is the probability for a photon to be scattered from the direction $\hat{\mathbf{u}}$ to the direction $\hat{\mathbf{v}}$ within an elementary solid angle $d\Omega(\hat{\mathbf{v}})$. The normalizing factor $(4\pi \text{ sr})^{-1}$ is not mandatory but follows the most usual convention, leading to simpler expressions (e.g., the isotropic phase function becomes simply $P(\hat{\mathbf{u}} \cdot \hat{\mathbf{v}}) = 1$, and phase functions are always dimensionless).

Asymmetry Parameter g For the simplest scattering cases (see, e.g., *Rayleigh scattering* and *Mie scattering* entries), P is a function of the only variable $\cos(\Theta) = \hat{\mathbf{u}} \cdot \hat{\mathbf{v}}$. Θ is called the *scattering angle*.

The average value of the scattering angle, g , defined as:

$$\begin{aligned} g &= \langle \cos \Theta \rangle \\ &= \frac{1}{4\pi \text{ sr}} \iint_{4\pi \text{ sr}} (\cos \Theta) P[\cos(\Theta)] d\Omega \\ &= \frac{1}{2} \int_{-1}^1 \mu p(\mu) d\mu \end{aligned} \quad (17)$$

with the standard substitution $\mu \stackrel{\text{def}}{=} \cos(\Theta)$. g is called the *asymmetry parameter*. $g = 1$ is equivalent to purely forward scattering, whereas $g = -1$ would be purely backwards scattering. Isotropic scattering implies $g = 0$, but the reciprocal assertion is not valid.

Source Term Expression Including Scattering

Taking scattering into account in Eq. (13) is possible, but requires a change in the expression of the source term S_v , namely:

$$\begin{aligned} S_v(\hat{\mathbf{u}}) &= (1 - \varpi_0) B_v(T) \\ &+ \frac{\varpi_0}{4\pi} \iint_{4\pi \text{ sr}} P(\hat{\mathbf{v}}, \hat{\mathbf{u}}) I_v(\hat{\mathbf{v}}) d\Omega(\hat{\mathbf{v}}) \end{aligned} \quad (18)$$

The fact that the source term for any beam direction $\hat{\mathbf{u}}$ includes contributions from spectral radiances in all directions $\hat{\mathbf{v}}$ implies that there is no more closed-form solutions when $\varpi_0 \neq 0$ ($\varpi_0 = 0$ leads to Eq. (14)). Various approximations to deal with this inconvenient fact are described in section “[Solving Methods and Approximations](#).”

Common Scattering Regimes

The two most common scattering regimes will be discussed in separate entries:

Rayleigh scattering is valid when the size of scatterers is much smaller than the radiation wavelength.

Mie scattering is valid for homogeneous, dielectrical and spherical scatterers of any radius.

An often used analytical phase function is the *Heney-Greenstein* phase function $P_{HG}(\Theta)$ defined by:

$$P_{HG}(\Theta) = (1 - g^2)(1 + g^2 - 2g \cos \Theta)^{-3/2} \quad (19)$$

which depends only on its asymmetry parameter g and the scattering angle Θ , and qualitatively similar to more physically realistic (albeit more complex) phase functions.

Polarization

All previous sections considered a *scalar* model of radiation, where knowing the sole (scalar) quantity I_v completely defined the radiation field. This model works well in absence of scattering and with purely thermal (therefore unpolarizing) sources, but scattering often leads to *polarization* of radiation, yielding additional insights on the scattering medium.

Stokes Formalism

The most common formalism to deal with polarization in atmospheric radiative transfer is to use the *Stokes* formalism, replacing I_v with a so-called

Stokes vector: (I_v, Q_v, U_v, V_v) , dependent on a local reference frame.

I : Total radiative intensity, equivalent to I_v the scalar formalism.

Q, U : Linearly polarized intensity components.

The dimensionless quantity $\frac{\sqrt{Q^2+U^2}}{I}$ is called *degree of (linear) polarization*.

V : Circularly polarized intensity. In planetary atmospheres, $V \ll U, Q$ usually.

Since scattering is the main cause of polarization in planetary atmospheres, a scalar phase function must be replaced by a *phase matrix* operating on the four components of the Stokes vector. Another technical difficulty arises from the necessity of aligning the Stokes reference frame with the scattering geometry, requiring the use of rotation matrices.

Basic Methodology

Observational Geometries

Angles

Except for in situ observations from the surface of solar system planets (Earth especially), most of our planetary atmospheric observations are performed remotely. From any location within a planetary atmosphere, there are therefore at least two (more often three) privileged directions:

- First, since planets are by definition in hydrostatic equilibrium, there is a well-defined local upwards (zenith) direction.
- Second, toward the observer's location.
- Third, if the radiation source is external (e.g., a star), toward this external illumination source.

These directions define the following angles:

- Between the upwards direction and the star's: *stellar (or solar) zenith angle (SZA)*
- Between the upwards direction and the observer's: *emission angle*

- Between the star's and the observer's: *phase angle*

Typology of Observations

When the emission angle is small enough so that the beam path in the atmosphere is comparable with the atmospheric vertical thickness, then observations are said to be *near nadir* (or *nadir* if emission angle is close to 0).

When emission angle approaches 90° , then observations are performed in *limb* geometry. Special sub-cases of limb observations arise when source-target-observer are nearly aligned:

- If the apparent source size is small compared to the observation target (e.g., a faraway star compared to a much closer planet), then it is an *occultation* observation.
- If the apparent source size is comparable or even larger than the target, then it is a *transit* observation, primary transit if the source is located behind the target ($\approx 180^\circ$ phase angle), secondary transit if the target is located behind the source ($\approx 0^\circ$ phase angle).

Plane-Parallel Approximation

In case of a near nadir observation, and since most planetary atmospheres are thin (more precisely, their scale height is small compared to the planetary radius), then the planetary curvature may be neglected in computations, with the atmosphere being divided in horizontal, homogeneous layers – only the vertical variations are considered. These simplifying assumptions are known as the *plane-parallel approximation*, and yield quantitative results that are valid up to a few percents when both emission angle (and SZA when relevant) do not exceed $\sim 70^\circ$.

In this approximation, it is customary to use a common τ_v coordinate along the vertical axis ($\hat{\mathbf{z}}$ unit vector in the local upwards direction), set to 0 in outer space and increasing downwards. In such a case, the slant optical depth τ_v^s for a radiation beam (along $\hat{\mathbf{u}}$) must be corrected by the *airmass* factor μ : $d\tau_v^s = -\mu d\tau_v$ with $\mu = \hat{\mathbf{z}} \cdot \hat{\mathbf{u}}$. Equation (13) using this new vertical τ_v coordinate then becomes:

$$\mu \frac{dI_v}{d\tau_v} = I_v - S_v \quad (20)$$

1D Spherical and Pseudo-spherical Geometry When emission angle and/or stellar zenith angles are too large for the plane-parallel approximation, it is possible to take into account the planetary curvature, while still ignoring horizontal variations. This is known as the *1D (radial) spherical geometry*. As a compromise, when the curvature may be taken into account only for the incoming and outgoing radiation beams by altering the expression of μ accordingly, while still computing multiple scattering within the atmosphere according to the plan-parallel formalism. Such a choice is labeled *pseudo-spherical geometry*.

Solving Methods and Approximations

Monte Carlo Methods

Monte Carlo (MC) methods provide approximate solutions to radiative transfer problems by simulating the history of a large (but finite) number of “photons” chosen to be representative of the whole radiation field. Radiative processes are modeled as random events (absorption, emission, scattering) following probability distributions matching the known medium properties (phase function, extinction, etc.).

Advantages These models can rely on very few simplifying assumptions. Therefore, they offer a “last resort” solution for complex situations (e.g., 3D scattering within spatially resolved clouds with no obvious symmetries). Another major advantage is that they can be shown to converge to the exact solution when the number of simulated photons becomes arbitrarily large.

Drawbacks The above mentioned convergence is a special case of the law of large numbers, and so improves very slowly with the number N of simulated photons ($\propto N^{-1/2}$). MC methods then require much longer computation times compared to other methods. As a consequence, their use is somewhat restricted to specific situations where

other methods fail and/or as validation schemes against which other methods are validated.

N -th Order Scattering Approximations

Another way to solve the radiative transfer equation with scattering is to distinguish between the order of scattering: first, the radiative transfer equation is analytically solved neglecting any scattering (zeroth order). Then, using this radiation field, the extra scattering source term may be estimated using Eq. (18), calculating a corrected radiation field (first-order approximation). This process may then be iterated and will converge to an exact solution.

Unfortunately, convergence is very slow and works well only in the limit of vanishing scattering optical depths ($\omega_0\tau \ll 1$). It is also quite cumbersome to compute past the very first most terms, so that only the first order *single scattering approximation* is encountered in practice.

N -Stream Approximations

N -stream approximations are a family of radiative transfer solving methods that parameterize the angular dependency of I_v . Common ways to proceed are (Acquista et al. 1981):

- Assigning constant values to I_v in several discrete angular intervals. A common form of the *two stream* approximation is given by, for example, $I(\tau, \mu > 0) = I^+(\tau)$; $I(\tau, \mu < 0) = I^-(\tau)$. This yields in turn $F(\tau) = \pi [I^+(\tau) - I^-(\tau)]$.
- Assuming a polynomial variation of $I(\tau, \mu)$ with respect to μ , also known as *Eddington approximation* (for a first degree polynomial).
- Choose a finite number of “representative” angles μ_i , and weights w_i , to compute angular integrals; $\int_{-1}^1 f(\mu) d\mu \approx \sum_{i=-M}^M w_i f(\mu_i)$. These are known as *quadrature approximations*.

All the aforementioned methods are computationally equivalent with the right choice of assumptions. Most numerical solvers use a special case known as the *discrete ordinate method*, where I_v is expanded in a truncated series of orthogonal Legendre polynomials with respect to μ . In such a case, integrals found in the source

function are transformed into a finite sum of Legendre polynomials components of I_v . Solving the radiative transfer equation therefore becomes a finite dimension linear algebra problem that can be solved through matrix inversion.

Doubling-Adding Method In realistic situations, optical properties of the atmosphere (ϖ_0 , phase function, etc.) are varying with (optical) depth, that is, planetary atmospheres are inhomogeneous media. In such a case, it is customary to divide the atmosphere into a finite number of optically thin and homogeneous layers, where radiative transfer equations can be solved to yield transmission/reflection matrices that link the angular components of I_v below and above these layers.

These transmission/reflection matrices for two given layers may then be used to compute the transmission/reflection for the two layers taken as a whole. A homogeneous, optically thick layer can therefore be divided in 2^n optically thin layers, with n iterations of *doubling*, whereas inhomogeneous media will require *adding* layers of different properties. In the two stream approximation, matrices R and T become scalar: $I^+(\tau_{\text{top}}) = RI^-(\tau_{\text{top}})$ and $I^-(\tau_{\text{bottom}}) = TI^+(\tau_{\text{top}})$. In this case, combining layers 1 and 2 yields:

$$T_{1+2} = \frac{T_1 T_2}{1 - R_1 R_2}; \quad R_{1+2} = R_1 + \frac{T_1^2 R_2}{1 - R_1 R_2} \quad (21)$$

The process is iterated until the transmission/reflection properties of the whole atmosphere are computed.

δ -Eddington Approximation Most phase functions exhibit a strong forward scattering peak that may be difficult to take into account with quadrature-based N -stream methods for reasonable values of N . A common way to circumvent this issue is to separate the forward peak, modeled as a Dirac δ distribution centered on $\Theta = 0$, from the smoother phase function $\tilde{P}$ at other scattering angles: $P(\Theta) = f\delta(\Theta) + (1 - f)\tilde{P}(\Theta)$. This is called the δ -Eddington approximation (Joseph et al. 1976).

Since purely forward scattering is equivalent to no scattering at all, this approximation results in scaling laws applied to derive new values τ' and ϖ'_0 of τ and ϖ_0 to be used with the smooth $\tilde{P}$ phase function, with:

$$\tau' = (1 - \varpi_0 f)\tau \quad (22a)$$

$$\varpi'_0 = \frac{(1 - f)\varpi_0}{1 - \varpi_0 f} \quad (22b)$$

k -Correlated Methods

The most exact and straightforward way to compute a full spectrum is the *line-by-line* method, where the spectrum is discretized in a finite number of frequencies, and radiative transfer equation solved independently for each frequency. A major drawback of this method arises when the optical properties of the medium exhibit strong spectral variations (e.g., multiple narrow spectral lines). In such a case, the required narrow spectral sampling results in prohibitively long computation times, even when the fully resolved spectrum is not needed (e.g., to compute spectrally integrated radiative heating rates in a general circulation model).

In such a case, within spectral bands where optical properties other than line absorption can be averaged smoothly, it becomes more interesting to compute the cumulative distribution of opacity in the considered spectral band. This distribution can be discretized, yielding a finite number of paired values ($\tau_i, \Delta g_i$) where Δg_i is the relative measure of the spectral interval where opacity (including line opacity) is close to τ_i , (with $\sum_i \Delta g_i = 1$ by definition). Radiative transfer equation may then be solved for each τ_i (yielding a “partial” radiance I_i) and the proper average value of I in the spectral band is finally given by $I = \sum_i \Delta g_i I_i$. This is called the k -distributed (or k -correlated) method. The main advantage of this method is that the number of total g_i bins required (typically a dozen) to reach a satisfying agreement with fully resolved line-by-line calculations is much smaller than the number of frequencies required to resolve the full spectrum.

Key Research Findings

Due to the ubiquity of radiative transfer in all astronomy-related fields, almost all of our observational knowledge about exoplanetary atmospheres makes use of radiative transfer at some point.

Applications

Near-Nadir Thermal Sounding

In plane-parallel formalism and for an optically thick atmosphere, the thermal emission measured by a remote observer can be expressed as:

$$\begin{aligned} I_v(\tau_v = 0, \mu) &= \int_{p=0}^{\infty} WF_v(\mu, p) B_v[T(p)] d \ln p \\ &= \int_{p=0}^{\infty} CF_v(\mu, p) d \ln p \end{aligned} \quad (23)$$

WF (CF resp.) is named *weight (contribution resp.) function*. Under simplifying hypotheses (isothermal hydrostatic atmosphere, no scattering, well mixed absorber whose cross-section is independent from pressure), it can be shown that WF follows a *Chapman function*, peaking within an atmospheric scale height around an altitude where $\tau_v = \mu$. Therefore, in pure nadir viewing, thermal sounding is most sensitive to the $\tau_v = 1$ level, and higher emission angles probe higher altitudes $\tau_v < 1$ due to the airmass factor which magnifies slant absorption.

It must be however noted that when the atmosphere is not isothermal, CF and WF can differ significantly due to the strong variation of $B_v(T)$ at higher frequencies. Also, scattering must be negligible for proper retrievals of temperature and composition detailed hereafter.

Temperature Sounding

When the absorber is well-mixed (e.g., CO_2 on Mars and Earth), the thermal spectrum can be used to retrieve the temperature profile within a given range of pressures: at frequencies where the absorber is less (more resp.) opaque, most of the

thermal emission originates from deeper (shallower resp.) layers, possibly including a surface contribution for optically thin atmospheres around telluric planets. In other words, the thermal spectrum, converted in brightness temperatures (see section “[Blackbody](#)”), is indicative of the physical temperature at the $\tau_v = \mu$ level.

As a consequence, and somewhat counter-intuitively, thermal spectrum may display *emission* as well as absorption lines, depending on the temperature gradient within the probed region ($dT/dz > 0$ leads to emission lines, since the probed altitude is located higher near the center of spectral lines; and conversely $dT/dz < 0$ leads to absorption lines). A corollary is that an isothermal profile $dT/dz = 0$ results in a featureless thermal spectrum whose brightness temperature is equal to the isothermal temperature.

Composition Sounding

Once the temperature profile $T(P)$ is known, for example, using the method above, information about the vertical profile of other absorbing species in the thermal spectrum may be measured, provided their spectral properties are known (through theoretical computations and/or laboratory measurements). The basic idea is as follows: measuring the brightness temperature in spectral lines caused by a given species of unknown vertical profile yields the pressure corresponding to the $\tau_v = \mu$ level, since $T(P)$ is known. This, in turn, can be converted into the column density of this absorbing species above the probed level. Therefore, the thermal spectrum contains information about the column densities over different levels as τ_v differs with ν , and differentiating these column densities yields the vertical abundance profile of the absorbing species within the probed pressure range.

Near-Nadir Scattered Light

Optically Thin Atmospheres

A commonly encountered situation is when clear, upper atmospheric layers (optically thin) are located above an optically thick “floor” (e.g., a planetary surface, or an optically thick cloud deck). In such a case, and provided that the

bidirectional reflectance distribution function (BRDF) $R(\hat{\mathbf{u}}, \hat{\mathbf{u}}')$ between the incidence direction $\hat{\mathbf{u}}$ and the emergence direction $\hat{\mathbf{u}}'$ (μ and μ' airmasses resp.) of the floor is known, scattering in the clear atmosphere can be safely neglected. Any absorption features in the reflected spectrum can then be used to retrieve the *column density* a of the absorbing species above the backscattering floor:

$$I(\tau = 0, \hat{\mathbf{u}}') = I(\tau = 0, \hat{\mathbf{u}})R(\hat{\mathbf{u}}, \hat{\mathbf{u}}') \times \exp\left[-\left(\frac{1}{\mu} + \frac{1}{\mu'}\right)\sigma_{\text{abs}}a\right] \quad (24)$$

In this case, absorbing species always exhibit absorption lines (dT/dz does not matter), since, unlike the thermal emission, no radiation sources are present in the atmosphere which is only illuminated from above.

Optically Thick Atmospheres

For a semi-infinite homogeneous atmosphere in the two stream formalism, it can be shown that its albedo Λ is given by:

$$\Lambda = \frac{1 - \sqrt{1 - \varpi_0}}{1 + \sqrt{1 + \varpi_0}} \quad (25)$$

and the average maximal optical depth $\langle\tau\rangle$ visited by backscattered photons is such as $\langle\tau\rangle \propto (1 - \varpi_0)^{-1/2}$. Therefore, observed albedo Λ is a good proxy for the maximal optical depth probed by the back-scattered radiation, which in turn can be used to estimate column densities of species located above this effective backscattering level as described above. Also, this implies that for nearly conservative scattering ($\varpi_0 \approx 1$), $\langle\tau\rangle \gg 1$, so that taking into account very deep atmospheric layers becomes mandatory.

Limb Observations

Opacity Amplification

In a purely limb geometry where the radiation beam has an impact parameter z_0 (closest approach altitude), and assuming that the atmospheric opacity is decreasing following a scale height H (equal to the atmospheric scale height for a well-mixed constituent), then the ratio

between the slant opacity along the tangent beam and the nadir optical depth above z_0 is given by:

$$\frac{\tau_{\text{slant}}(z_0)}{\tau_{\text{nadir}}(z_0)} \approx \sqrt{\frac{2\pi(R + z_0)}{H}} \quad (26)$$

Since $R \gg H$, this results in a dramatic opacity amplification that is especially well-suited to measure minute amounts of absorbers/scatterers in a narrow altitude range centered on z_0 . Conversely, layers located below an optical depth $\tau_{\text{nadir}} \sim \sqrt{H/R} \ll 1$ cannot be accessed through limb observations, unless using a very powerful illumination source (e.g., the Sun for solar system atmospheres) visible even through large values of τ . This is also the case for transit spectroscopy of extrasolar atmospheres.

Inhomogeneous Atmospheres

When spherical symmetry can be assumed and occultation geometry can be precisely measured, a commonly used method to retrieve vertical profiles of opacity is the *onion peeling method*: during the ingress/egress of a star through a planetary atmosphere, the properties of the topmost atmospheric layer where extinction can be measured can be derived assuming a homogeneous layer. Once the topmost layer is characterized, then observations within the second layer located immediately below can also be retrieved, and the process can be repeated until extinction becomes too large. This method requires an excellent knowledge of the tangent altitude of the occulted star through the planetary atmosphere, and a suitable trade-off between signal-to-noise and vertical resolution through the required integration time.

Refractivity Measurements

In the radio range where atmosphere is almost transparent, the differential refraction of tangent radio beams originating from, for example, an orbiter – the lower part of the beam being more refracted than the upper part – leads to a divergent spread and additional dimming of the incoming beam compared to straight-line propagation out of the atmosphere, as well as an additional phase shift. This additional dimming is inversely proportional to the atmospheric scale height, so that

temperature profiling (assuming hydrostatic equilibrium) is possible in atmospheric layers that are located too deep for their thermal radiation to be used.

Radiative Balance

Besides remote sensing, radiative transfer is fundamental to understand the energy fluxes within an atmosphere and its thermal structure. As an example, when the effective altitude of stellar radiation absorption is located below the effective altitude of thermal infrared emission to outer space, then the infamous phenomenon of *greenhouse effect* occurs.

Another quantity derived from radiative transfer calculations and important to assess the dominant physical processes occurring in a planetary atmosphere is the *radiative time constant* t_{rad} , defined as:

$$\frac{\partial \Delta T}{\partial t} = -\frac{\Delta T}{t_{\text{rad}}} \quad (27)$$

where ΔT is a small temperature disturbance with respect to the local radiative equilibrium temperature T : $\Delta T \ll T$. t_{rad} can thus be thought as a relaxation time toward radiative equilibrium. It can be shown that $t_{\text{rad}} \propto \frac{\rho C_p}{T^3}$, so that radiative processes act much faster for hotter atmospheres.

Future Directions

The ever-increasing available computing power enables more and more sophisticated and exact approximations in solving the radiative transfer equation. Therefore, most of the effort goes into a better determination of the optical properties of atmospheric layers:

- Better determination of aerosol phase functions, beyond the simpler models (Rayleigh, Mie).
- Better theoretical models of absorption line shapes.
- Theoretical improvements and laboratory measurements of continuum gaseous absorption for a wider range of temperature and pressure. These two latter items together constrain the spectral location and transparency of so-called

atmospheric windows and therefore crucial for radiative budget balance and remote sensing.

- Expand and improve the existing databases for absorption lines and continuum gaseous opacity with weaker lines and a more diverse array of gaseous species, especially for “exotic” exoplanet atmospheres from a solar system centered point of view.

Definition

Radio astronomy describes the techniques employed, from antennas to receivers, to receive and measure long wavelength electromagnetic radiation (radio waves). The specificity of these techniques, by contrast with optical or high-energy astronomy, is the coherent detection of the wave electric field (amplitude E and phase φ), instead of the mere intensity ($\langle E^2 \rangle_{\Delta t}$). This makes ► [interferometry](#) easier, compensating for the poor angular resolution intrinsic to long wavelengths. Radio emissions are produced by processes often different from those in the optical range. These include cyclotron and synchrotron emissions, bremsstrahlung, molecular and atomic transitions, and various coherent processes. Radio astronomy is especially adapted to probing ► [plasmas](#) (ionized/magnetized matter) as well as cold matter.

History

Radio astronomy is a recent branch of astronomy, born in the 1930s at low frequencies (22 MHz) with K. Jansky's detection of the radio emission from terrestrial lightning and from the Galactic center. It strongly developed along with RADAR techniques during World War II, after which detection of the Sun at 0.15, 3, and 10 GHz was reported. Discoveries accumulated during the late 1940s and 1950s, with the discovery of the radio emissions from the Moon (thermal), radio galaxies (nonthermal), and Jupiter (coherent). A major milestone was the discovery of the ubiquitous 21-cm line due to the hyperfine structure of neutral hydrogen (H_I), allowing astronomers to map the Milky Way as well as to observe the distant Universe. Major radio observatories were created in the 1950s (Cambridge, Jodrell Bank, Westerbork, Parkes, Greenbank, Arecibo, Nançay...). The 1960s saw the discovery of pulsars, quasars, the natural radio emission of the Earth itself, the first measurements of molecular lines, and the discovery in 1965 of the famous 3 K radiation, relic and proof of the Big Bang. In the 1960s and 1970s, arrays of antennas and interferometers were developed, along with the underlying theory (aperture synthesis). The 1970s and 1980s brought the first era of radio astronomy from space, with RAE satellites, Voyager space probes, and many others. Radio astronomy conquered ever-higher frequencies, with the IRAM instruments dominating the millimeter range since the 1980s. The 1990s saw the discovery of the fluctuations of the 3 K radiation by COBE, as well as the discovery of the first extra-solar planet (around a pulsar in 1992). The years 2000–2010 mark the start of giant arrays (LOFAR, ► [ALMA](#), precursors for SKA...) as well as always more sophisticated spaceborne radio instruments (onboard Cassini, Stereo, Parker Solar Probe, or Planck...).

Overview

Specificity

The radio frequency range is defined by two criteria: (1) the transparency of the Earth's

atmosphere, between atmospheric absorption at short wavelengths and ionospheric reflection at long wavelengths defining a broad window $\sim 10 \text{ MHz} - 1 \text{ THz}$ ($\lambda = 30 \text{ m}$ to $\sim 0.3 \text{ mm}$); (2) the capability to coherently detect the wave electric field (amplitude E and phase ϕ), instead of its mere intensity ($\langle E^2 \rangle_{\Delta t}$), only limited by available technology (oscillators, mixers...). The upper frequency limit increases with time, reaching presently the THz range. For example, the instrument HIFI onboard the Herschel satellite covers the range 490–1902 GHz, using coherent (heterodyne – see below) detection techniques and superconducting (SIS) mixers.

Radioastronomy permits us to investigate sources and physical processes different from the optical range. For example (Fig. 1), radio images of Jupiter are dominated by its huge radiation belts, emitting intense polarized synchrotron emission; radio galaxies are generally two-lobed in radio, revealing immense jets; pulsars (rotating magnetized neutron stars) were discovered and long known only in the radio range. About physical processes, the Planck and Wien laws tell us that the thermal emission of cold bodies (typically $< 100 \text{ K}$) dominates in the radio range, in which the spectrum is simply proportional to frequency squared (Rayleigh-Jeans law). But many nonthermal emission processes are also active: cyclotron and synchrotron, bremsstrahlung (free-free), atomic and molecular lines, and various coherent processes. Wave scattering by dust or atomic Hydrogen varies as $1/\lambda^n$ and is thus weak in the radio range, permitting the observation of a large fraction of the Milky Way, including its central regions.

Technical specificities of the radio range include a low photon noise even at low fluxes (each photon carries little energy), poor angular resolution (λ/D at large λ), high temperature of the sky (Galactic background at longer wavelengths, of temperature $T_{\text{sky}} \sim 60/\lambda^{2.55} \text{ K}$ with λ in m), and strong pollution by natural and man-made radio frequency interference (RFI), particularly at longer wavelengths. These inconveniences are compensated by the data processing possibilities offered by coherent detection and high time and frequency resolutions, e.g., using a combination

Radio Astronomy, Fig. 1 Radio astronomical sources (from left to right and top to bottom): Very Long Baseline Interferometry (VLBI) observations of quasar 3C273 at two epochs; 3 K fluctuations map by Cosmic Background

Explorer (COBE); Radio image of the lobes of the Cygnus A radio galaxy at 5 GHz; Sketch of a pulsar environment and radio beams; Jupiter's synchrotron map from radiation belts

of phased arrays of antennas, interferometry, and RFI mitigation techniques. Both RFI and the sky background are lower in the mm/sub-mm domains, while emission from dust grains becomes important in the far infrared (FIR). Ground-based mm/sub-mm/FIR observations are strongly affected by the Earth's atmospheric emission and absorption. Observations at these wavelengths require space observatories, such as the ESA cornerstone mission Herschel which observes in the 55–670 μm range (490 GHz–6 THz).

Polarization and Propagation

Coherent detection allows for accurate measurements of wave polarization (which characterizes the wave electric field in the plane perpendicular to the wave vector). Polarization may linear, circular in the right-hand or left-hand sense, or elliptical. A fraction of the wave energy may be unpolarized, i.e., correspond to wave packets with random E-field orientation in the wave plane. Wave intensity and polarization is fully described by the 4 Stokes parameters I (intensity), Q, U (linear polarization), and V (circular polarization), the polarized fraction being $(Q^2 + U^2 + V^2)^{1/2}/I$. It should be noted

that wave polarization can be uniquely decomposed on an orthogonal basis formed by two perpendicular linear polarizations or two opposed circular (RH and LH) polarizations.

Radio propagation depends on the electron density N_e and the magnetic field B of the traversed media, which in return allows astronomers to probe magnetized astrophysical plasmas. There are three important propagation effects for a wave at frequency f propagating at angle θ from the ambient B-field:

- Cutoff of radio waves with $f \leq f_{pe}$, and reflexion for $f \leq f_{pe}/\cos\theta$, where $f_{pe} \propto N_e^{1/2}$ is the plasma frequency and θ is the wave incidence angle relative to the normal to the plasma boundary; this explains the ionospheric cutoff at ~ 10 MHz, preventing ground-based observation of radio waves of lower frequency, as well as permitting terrestrial short wave propagation by reflection below the ionosphere.
- Dispersion of broadband signals, leading to an arrival time delay proportional to f^{-2} and to the dispersion measure $DM = \int_L N_e dL$, the integral along the line of sight of the electron density; this explains the time-frequency shape of pulsar signals.

- Rotation of the linear polarization plane of a linear or elliptical wave traveling through a magnetized plasma (Faraday effect), where the angle of rotation is proportional to DM, f^{-2} , and the magnetic field $B_{\parallel}$ along the propagation path.

Additionally, random fluctuations of plasma parameters such as the electron density lead to weak or strong scintillation of radio waves, resulting in fluctuations of source intensity and position and in temporal and spectral broadening of radio emissions.

Basic Methodology

Basics

Radioastronomy consist of collecting, detecting, and measuring weak natural radio signals in the presence of noise, natural (sky background, lightning...) or man-made (radars, radio/TV broadcasting, computer clocks, etc.), including the noise produced by the radio telescope itself. The receiving antenna element (electric dipole or horn) can be preceded by a collector (e.g., a parabola) concentrating the incident energy. It is characterized by a radiation pattern or directional gain $G(\theta, \varphi)$, and an effective area $A_{\text{eff}}(\theta, \varphi) = G(\theta, \varphi) \lambda^2 / 4\pi$, where θ and φ are angular coordinates defining a position on the sky. After integrating over all angles, these quantities satisfy the relations:

$$\int_{4\pi} G(\theta, \varphi) d\Omega = 4\pi \quad \text{and} \quad \int_{4\pi} A_{\text{eff}}(\theta, \varphi) d\Omega = \lambda^2$$

For a directional antenna with quasi-constant gain $G = 4\pi/\Omega$ over the solid angle Ω (called the main lobe) and negligible elsewhere (secondary lobes), one has $A_{\text{eff}}\Omega = \lambda^2$ in the direction of the main lobe. The spectral power $P(f)$ [WHz^{-1}] received by a radio telescope can be expressed as a temperature, called antenna temperature, via $P = k T_A$ (with k the Boltzmann constant). In the general case of a radio source of brightness

described by $T(\theta, \varphi)$, the measured antenna temperature is

$$T_A = 1/4\pi \times \int_{\text{source}} T(\theta, \varphi) \times G(\theta, \varphi) d\Omega$$

As a consequence, the antenna temperature measured by a directional radio telescope is simply the source temperature averaged over the main antenna lobe ($T_A = \langle T \rangle$) if the source is more extended than the main lobe, or this quantity affected by a dilution factor ($T_A = \langle T \rangle \Omega_{\text{source}} / \Omega_{\text{main lobe}}$) otherwise. When observing an extended black body, the measured T_A is the brightness temperature and, thus, physical temperature of the source. Conversely for an unresolved source (unknown Ω_{source}), the antenna temperature can be determined, but not the brightness temperature.

The flux density received by the radio telescope is S [$\text{Wm}^{-2}\text{Hz}^{-1}$] = (2) kT_A/A_{eff} . The factor (2) expresses the fact that a polarized antenna observing an unpolarized source transmits only half of the incident intensity or power to the receiver.

Due to the small size and weak intensity of natural radio sources, T_A is often very small. Source detection requires T_A to be larger than the fluctuations – generally Gaussian – of the noise, whose dominant origin may be the sky background of temperature T_{sky} (dominant at low frequencies) or the Nyquist noise of resistive parts of the instrument of temperature T_{system} (dominant at high frequencies). When measuring a signal or noise of average temperature T with a time integration τ and a spectral bandwidth b , the standard deviation of consecutive measurements is $\sigma \approx T/(b\tau)^{1/2}$. Hence, the definitions of the “noise temperature” $T_N = (T_{\text{sky}} + T_{\text{system}})/(b\tau)^{1/2}$, of the signal-to-noise ratio $\text{SNR} = T_A/T_N$, and of the minimum detectable flux density $S_{\text{min}} = (2) kT_N/A_{\text{eff}}$. The latter formula shows that the sensitivity increases with the effective area of the radio telescope. The limitation due to T_{sky} can be reduced only by temporal and spectral integration, whereas that due to T_{system} can be reduced via low-noise electronics or cryogeny (down to 10–20 K).

Receivers

Parameters defining a receiver include total observable frequency range, temporal and spectral resolution, gain, stability, dynamic range and linearity, system temperature, and output data rate. Practical implementations are very diverse, analog or digital, swept-frequency or multi-channel. . . , each with specific advantages and inconveniences.

As digitization rate is presently limited to $f_{\text{sampling}} \sim 1$ GHz, coherent receivers generally rely on the heterodyne technique, in which the frequency band of width Δf centered at frequency f (i.e., $f \pm \Delta f/2$) is mixed with a local oscillator (f_{LO}) for downshifting to low frequencies ($f - f_{\text{LO}} \pm \Delta f/2$), before digitization at f_{sampling} . Digitization of signals at frequencies $> f_{\text{sampling}}/2$ can also be performed via direct down conversion associated to adequate band filtering. Spectrometers for modern digital receivers include correlators, fast Fourier transform spectrometers, polyphase filter banks, or waveform samplers. Receiver chips (DSPs, FPGAs) are increasingly used to run real-time RFI mitigation or burst detection.

Antennas, Arrays, and Imagery

Radio telescopes often consist of large reflectors (there is no radio lens) such as the one in Fig. 2, equipped with a single focal antenna or an antenna

array (see below). At centimeter-to-decimeter wavelengths, single dishes have dimensions typically $D \leq 100$ m and thus an angular resolution no better than $\sim 1'$. A way to increase the size, and hence the resolution, is to build the radio telescope as an array of N antennas with maximum separation $d \gg D$, whose signals are coherently summed or multiplied, giving access to an angular resolution $\sim \lambda/d \ll \lambda/D$. The sensitivity also increases as the number of antennas in the array (i.e., $\propto N \times A_{\text{eff}}$).

When the array is used as an interferometer, signals from pairs of antennas are correlated (multiplied). The contrast and phase of the resulting interference fringes is simply related to the Fourier transform of the spatial distribution of source intensity. The Fourier coordinates (u, v) describing the spatial (angular) frequencies of the interference pattern are never completely explored. Aperture synthesis deals with optimization of the (u, v) plane coverage. In order to reach very high angular resolutions (down to 10^{-4} arcsec), very long baseline interferometry (**VLBI**) uses intercontinental baselines. The signal is then recorded at each antenna along with an accurate time reference (e.g., atomic clock) and correlated offline.

As the field of view (FoV) decreases with increasing telescope size, interferometers made of large antennas are not adapted to sky surveys.

Radio Astronomy,

Fig. 2 The 100-m Effelsberg radio telescope

A way to combine high sensitivity, good angular resolution, and a large FoV is to form a phased-array from many near-isotropic antennas (e.g., electric dipoles). Beamforming is the coherent summation of antenna signals, phased to produce a narrow beam pointed at a selected direction in the sky, within the envelope imposed by the diagram of each elementary antenna. In addition to the ability to steer electronically and near-instantaneously the radio telescope main beam, modern electronics allows one to form simultaneously a large number of narrow beams pointed at different directions. Such multibeam techniques are used in focal plane arrays to provide multipixel matrices (up to tens of pixels) at the focus of large reflectors, expanding their FoV, as well as in “aperture arrays” of many thousands of antennas able to produce hundreds of simultaneous beams. The latter enable fast and sensitive wide-field surveys, as well as RFI-nulling techniques.

Key Research Findings

Large Instruments and Perspectives for Astrobiology

The revolution in digital calibration and imaging techniques in the past 25 years enabled the construction and exploitation of several antenna arrays.

At high frequencies, the Atacama Large Millimeter/submillimeter Array (ALMA, 40–950 GHz) is the major millimeter-submillimeter interferometer since 2013, in which 66 parabolas of 7 and 12 m forming baselines up to 16 km and ensuring subarcsecond resolution. Astrobiology-related observations of ALMA especially consist in the direct imaging of young forming giant planets in protoplanetary disks (as hot clumps and the gaps that they form within disks), and possibly very young systems in the nearest star-forming regions, via their thermal emission. Several images of protoplanetary disks were obtained following the first spectacular image of the HL Tau system (Fig. 3). Other interferometers such as the VLA or ATCA aim at detecting circularly polarized cyclotron-Maser radio emission produced at the local cyclotron frequency f_{ce} by magnetized stars or star-planet interactions (SPI).

At low frequencies, the major instrument is the LOW Frequency ARray (LOFAR), a European interferometer of phased arrays in the range 30–250 MHz (Fig. 4). Other arrays include the LWA, MWA, UTR-2, and NenuFAR (the large low-frequency – 10–85 MHz – extension of LOFAR in Nançay). Circularly polarized radio emission has been recently detected in LOFAR imaging surveys (e.g., from GJ 1151 or CR Draconis) and in targeted beamformed observations (Tau Boötes), and interpreted as the nonthermal auroral Jupiter-like radio emission from exoplanetary magnetospheres or resulting from plasma SPI (Fig. 3).

Applications

When confirmed and expanded, the above detections at low frequencies will open the new field of compared exo-magnetospheric physics. Theoretical predictions of radio emission power are based on a radio-magnetic scaling law. An interpretative frame of their characteristics has been proposed on the basis of simulations developed from Solar system radio emissions (from Jupiter, Saturn. . .), that show that radio detection of exoplanets will bring information of their magnetic field (amplitude, offset, tilt), rotation period, orbit inclination, and on the physics of SPI. The existence of a magnetosphere around an exoplanet is considered as a factor favoring its habitability.

Future Directions

Most of the recent radio arrays cited above, plus instruments such as ASKAP in Australia or MeerKAT in South Africa, are pathfinders and precursors of the giant Square Kilometer Array (SKA), presently in construction in these two countries, and that will be the world’s ultimate twenty-first century radio telescope in the range 50 MHz – 15 GHz. It will gather hundreds of thousands low-frequency antennas and hundreds of ~ 15 m parabolas to reach $A_{\text{eff}} \sim 4 \times 10^4$ to $> 10^6 \text{ m}^2$ and provide thus an extreme sensitivity across its entire band. SKA will address both planetary formation and

Radio Astronomy, Fig. 3 Radio astronomy observations relevant to Astrobiology (from left to right and top to bottom): ALMA images at $\lambda \sim 1$ mm of HL Tau and of MWC 758 (stars surrounded by a protoplanetary disk showing planet formation gaps and clumps – ALMA/Brogan et al. 2015, Dong et al. 2018); Artist view of stellar wind-magnetosphere interaction expected to drive auroral

radio emission; LOFAR detection of the polarized variable source GJ 1151 (Vedantham et al. 2020), and dynamic spectrum of CR Draconis (Callingham et al. 2021), in imaging mode; LOFAR tentative detection of weak Tau Boötis radio bursts (Turner et al. 2021) in beamforming mode

Radio Astronomy, Fig. 4 LOFAR, the LOw Frequency ARray: insets show individual stations across Europe, with their low-frequency antennas and high-frequency antenna tiles

magnetospheric or star-planet driven radio emissions. For future decades, a “LOFAR-on-the-Moon” project is under study, which would benefit from a radio-quiet environment and of the quasi-absence of an ionosphere, allowing us to explore the frequency range below 10 MHz. As an alternative, large clusters of low-frequency antennas in space forming a free-flying interferometer are under study.

History

During the second half of the nineteenth century, the electromagnetic theories of James Clerk Maxwell (1831–1879) and the experiments of Heinrich Hertz (1857–1894) permitted scientists to consider the possibility of an emission of radio waves by the stars or the Sun. According to the German physicist Hermann Ebert (1861–1913) in 1892, the observation of electric discharges in vacuum tubes were conducted to investigate the possible existence of Hertzian (radio) waves emitted by the Sun. Admitting the validity of Maxwell's theory, the French physicist Charles Nordmann (1881–1940) was convinced that high-altitude observations might succeed in detecting those solar radio waves. But despite using a 175-m antenna placed almost at the top of Mont Blanc, he detected no waves because of a lack of sensitivity.

The detection of “cosmic static”, i.e., radio waves of extraterrestrial origin, was made for the first time by the American radio engineer Karl Guthe Jansky (1905–1950) in 1932. Working for the Bell Laboratories, Jansky made this discovery while identifying the sources of the static which interfered with radiotelephones. He found that this static was composed of emission from both local sources such as thunderstorms and an extraterrestrial source. After a year of study, Jansky could come to the conclusion that this extraterrestrial emission was radio emission from the center of

the Milky Way. Although the announcement of this discovery was highly popular, it had no response from the astronomical community.

The only one who seemed interested to pursue the Jansky's work was the American radio engineer Grote Reber (1911–2002). Reber wanted to achieve two objectives: to determine the variation with the position on the sky of the intensity of extraterrestrial radio emission at any given wavelength and to determine the variation with wavelength of this intensity at any given position. So, he needed simultaneously both high angular resolution and a wide band of wavelengths. For this, he decided to construct a paraboloidal reflector, and he tried to make the first radio map of the sky, at a wavelength of 160 MHz. He questioned current optical astronomy because he found that the position of the maximum radio emission was some 30° off the then-accepted galactic center. These results were obtained during World War II, but after the war, the investigations in celestial radio waves were much slower in the USA than in Britain or Australia.

The main wartime discoveries were made in Britain by James Stanley Hey (1909–2000), and his colleagues at the Army Operational Research Group. Working to improve the effectiveness of army radar equipment by studying sources of interference, this group made three unexpected discoveries: the detection of radio emission from the Sun, the detection of radar echoes from meteor trails, and the localization of a radio noise in the direction of Cygnus. Hey's work became common knowledge within two groups in the UK after war: the department of physics in Manchester and the Radiophysics Group at the Cavendish Laboratory, Cambridge. After the failure of the study of cosmic rays by means of radio waves, radio physicists in Manchester became concerned with the determination of radar echoes from meteors, to know if meteor showers were of interstellar origin or were confined to the solar system. By the early 1950s, this line of investigation began to decline, and groups in Manchester and Cambridge all became interested in the study of “radio stars.” This was the same in Australia, where radio engineers such as John Gatenby Bolton (1922–1993) and Gordon James Stanley (1921–2001), working at the Radiophysics Laboratory in Sidney, made

important studies of a source in Cygnus. Above all, they made the first identification of a radio source, Taurus A, with an optical object, the Crab Nebula, leading to the first intimate link between the radio investigator and the classical astronomer. British and Australian successes paved the way to a new science, radio astronomy and incited scientists in other countries to enter the new field. By the mid-1950s, an international community emerged, particularly in France, Canada, the USA, USSR, and Japan.

From a technical point of view, three types of radio telescopes have been used until now. The first one consists of a single antenna, often associated with a paraboloidal reflector. This type of radio telescope only permits observation of objects whose angular extension is higher than 100 arcsec (certainly no longer true, and in any case not a fundamental limit of single dish radio telescopes). Larger and larger collecting areas were reached during the 1960s, permitting astronomers to go to ever shorter wavelengths. The radio telescope of Arecibo (Porto Rico) is emblematic of this evolution: this spherical reflector, 300-m in diameter, was finished in 1965.

The second type of radio telescopes is constituted of a number of antennas that are physically connected so that the electrical signals may be directly compared. This type of instrument is called an interferometer, since it uses the principles of interferometry to synthesize a very large effective aperture from a number of small elements. The signals from a source alternately arrive in phase and out of phase as the Earth rotates and cause a change in the difference in path from the radio source to the different elements (telescopes) of the interferometer, producing interference fringes similar to the ones in an optical interferometer. This is the case of the method called "aperture synthesis" invented and developed by the British radio physicist Martin Ryle (1918–1984) in 1962 and that led him to the Nobel prize in 1974, shared with Antony Hewish (1924–). This technique permits the mapping of radio objects with high angular resolution. Examples of such facilities are the Westerbork Synthesis Radio Telescope (WSRT) built in Holland in 1972, which operates with eight 13-m dishes, and

the Very Large Array (VLA), opened in 1980 near Socorro, New Mexico, which achieves an angular resolution below 0.1 arcsec with its twenty-seven 25-m antennas.

The third type of radio telescope is made of independent and separate antennas synchronized by the means of atomic clocks: by this means, sub-milliarcsecond angular resolution became possible. This is illustrated by the very long baseline interferometry technique (VLBI), in which antennas are spaced more than a few tens of kilometers apart.

It's important as well to note that a radio telescope consists of an antenna and a radio receiver used to detect and amplify the signals. The sensitivity of the receiver was thus a crucial element in the development of radio astronomy. At the beginning (Jansky, Reber), valve receivers were used (diode, triode), which then gave way to transistors. Some unusual receivers such as the parametric amplifier and the maser were also employed at centimeter wavelengths; it can be noted that the discovery of the cosmic background radiation by Arno Allan Penzias (1933–) and Robert Wilson Robert Woodrow Wilson (1936–) in 1964 (for which they received the Nobel Prize in 1978) was made using a very low noise maser amplifier. Further developments of field-effect transistors (FET) and high electron mobility transistors (HEMT) resulted in receivers with nearly quantum noise when cooled to 15 K: nowadays, HEMTs can pick out, from a sea of noise, minor 10 K signals sent out by interstellar molecules.

Historically, radio observations started at meter wavelengths and were extended to centimeter, then to millimeter, and finally to sub-mm wavelengths. The large range of wavelength has permitted achievement of important and numerous results in astrophysics, cosmology, and, now, astrobiology. As far back as 1942, the Sun had been identified by Hey as a radio emitter, followed by Reber and Southworth. A critically important step has been the development of radio spectroscopy, particularly when centimeter and shorter wavelengths were available for study: for instance, the first detection of the atomic hydrogen line at 1427 MHz (21 cm) made by Harold Irving Ewen (1922–) and Edward Mills Purcell

(1912–1997) (who received the Nobel prize in 1952 for his research in nuclear magnetism) inaugurated a new era of galactic investigations. This discovery opened up possibilities to detect hydrogen clouds in the galactic plane and to determine the spiral structure of our galaxy and of galactic kinematics by application of the Doppler effect. In the short centimeter and millimeter wavelengths, molecular lines could be studied and have given important information on the composition and physical state of the interstellar medium in our galaxy and external galaxies, as well as on solar system objects such as comets and planetary atmospheres. OH was the first molecule to be detected by radio observation in 1963 by Weinberg; it was subsequently analyzed as a natural maser in 1965. Numerous organic molecules were then detected: H_2CO in 1969; CO, CN, HCN, and CH_3OH in 1970; H_3COH and H_2CS in 1971; $(\text{CH}_3)_2\text{O}$ in 1972; etc.: these discoveries have constituted important steps in the emergence of interstellar chemistry and astrobiology. Radio astronomy has as well permitted the identification of new stellar objects: in the 1960s, for instance, pulsars and quasars were identified as powerful radio emitters.

Nowadays, the Atacama Large Array Millimeter (ALMA) is the most recent international project in the field of radio astronomy and is viewed as permitting a new age of research in astronomy. A joint project between Europe (ESO), North America (NSF), and Japan, ALMA will encompass 64 interconnected 12-m antennas at a unique high-altitude site at Chajnantor in the Atacama region of northern Chile. By studying mm and sub-mm wavelength radiation, ALMA will try to understand such processes as planet and star formation, formation of early galaxies and galaxy clusters, and the formation of organic molecules in space.

Radioactive Heating

Tilman Spohn
 International Space Science Institute, Bern,
 Switzerland

Definition

Radioactive heating refers to the energy dissipated in the interiors of planets, satellites, or ► [asteroids](#) as a consequence of the radioactive decay of

radioactive isotopes (see ► [radiochemistry](#)). Radioactive ► [isotopes](#) are characterized by their decay energies and their ► [half-lives](#). The radioactive isotopes of importance on the timescale of a billion years are the so-called long-lived isotopes uranium ^{238}U , ^{235}U , thorium ^{232}Th , and potassium ^{40}K . Short-lived isotopes may have heated the planets in their early evolutions. The most effective short-lived isotope is ^{26}Al , because of its abundance and decay energy. The concentrations of these elements differ between planets depending on their formation and chemical evolution. Partial melting and differentiation is a mechanism for redistributing radioactive isotopes between ► [crust](#) and ► [mantle](#) reservoirs.

Radioactivity

Francis Albarède
Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Keywords

Atoms · Radioactive decay

Definition

Radioactivity is a spontaneous and irreversible transformation of the atomic nucleus. It is the

source of ionizing particles (α particles, comprising two protons and two neutrons; β^- rays or electrons; and strong electromagnetic radiations (γ rays)). Radioactive decay is archetypal of Poisson processes, which take place with a constant probability per unit of time. Radioactivity powers the energy flow of planetary interiors. It is also the theoretical basis of dating methods that are used to measure the age of rocky planets (geochronology).

History

After a serendipitous discovery by French physicist Henri Becquerel in 1896, radioactive elements were methodically investigated by Marie Curie. In 1928, George Gamow demonstrated that α decay was due to quantum mechanical tunneling, and in 1934 Enrico Fermi provided a successful explanation of the β^- decay involving neutrinos.

Overview

Radioactivity involves the gigantic energies of the strong, short-range, nuclear force, which are on the order of a few millions of eV (electron volt) per nucleon. In contrast, mineral reactions and thermal agitation involve energies in the eV range. Rates of decay are therefore independent of the chemical, thermal, and mineralogical environment of the element in question and are also insensitive to pressure, which only affects the outermost electron shells. Decay rates have not measurably varied with time. The three most common radioactive decay processes are the following:

1. The α (alpha) process is the emission of an alpha particle (He nucleus). The nucleus is held together by the short-range attractive strong force between adjacent protons and neutrons, and the total binding energy increases linearly with mass. In contrast, the electromagnetic force, which tends to pry the positively charged protons apart, is weaker but acts over a

broader range, so that it involves the entire nucleus: it varies with the total number of proton pairs and therefore with the *squared* number of protons. Heavy nuclei become knobby and wobbly and some parts tend to detach. Because both the neutrons and protons are paired, the α particle does not transport angular momentum and its ejection from the nucleus is facilitated. The α process is a consequence of the quantum tunnel effect: although the potential barrier opposing the ejection of an α particle is much greater than the energy gain resulting from separation, there is still a non-zero probability that ejection will occur. The alpha particle is a helium nucleus and alpha decay is the source of essentially all the ^4He in the Earth. Mass loss between the original nucleus and the resulting particles is compensated by emission of γ rays, which account for most of the heating of planetary interiors (from U and Th). For example, $^{147}\text{Sm} \rightarrow ^{143}\text{Nd} + \alpha$.

- The β^- (beta minus) process involves the emission of an electron and is most common for neutron-rich [▶ nuclides](#). It calls for the effect of the unfamiliar short-range weak interaction. The lower energy of the proton-neutron interaction with respect to that of similar nucleons favors a nucleus with an equal number of protons and neutrons. When $N > Z$ (atomic number), excess energy is therefore released by converting a neutron into a proton and a W^- boson, which itself decays into an electron and an antineutrino. Neutrinos have no mass and do not interact with matter, yet they carry a large fraction of the decay energy, which often renders the measurement of beta decay constants imprecise. For example, $^{87}\text{Rb} \rightarrow ^{87}\text{Sr} + e^- + \bar{\nu}$ (e^- is an electron and $\bar{\nu}$ an antineutrino).
- Capture of an electron of the K shell is a less frequent process. For example, $^{40}\text{K} + e^- \rightarrow ^{40}\text{Ar}$.

A nuclide may be unstable with respect to two decay processes simultaneously, and the probabilities of decomposition by each process are additive. For example, ^{40}K decays dually into ^{40}Ca by β^- emission and into ^{40}Ar by electron capture; this is known as a branched mode of radioactive decay.

Cosmic rays · Radioactive isotope · Radioactivity

Definition

Radiochemistry is a field of chemistry concerned with radioactive materials. Research objectives of radiochemistry include the following:

- Distributions and transformations of radioactive nuclides
- Synthesis of artificial nuclides
- Separation and purification of radioactive isotopes
- Chemical properties of radioactive elements and their compounds
- Chemical action of knock-on atoms associated with radioactive decay
- Utilization of radioactive isotopes, i.e., utilization as a radioactive tracer or for isotope dating

This field was launched by the discovery of radioactivity by Becquerel in 1896.

Overview

Radioactive isotopes transform via nuclear decay and emit mainly three types of radiation, which are called alpha, beta, or gamma radiation.

1. Alpha radiation – the emission of an alpha particle (which contains 2 protons and 2 neutrons) from an atomic nucleus. When this occurs, the atom's atomic mass will decrease by 4 units and atomic number will decrease by 2.
2. Beta radiation – the transmutation of a neutron into an electron and a proton. After this happens, the electron is emitted from the nucleus into the electron cloud.
3. Gamma radiation – the emission of electromagnetic energy from the nucleus of an atom. This usually occurs during alpha- or beta-radioactive decay.

These three types of radiation can be distinguished by their differences in penetrating power. An alpha particle, the equivalent to a helium nucleus, is stopped quite easily by, for example, a few centimeters in air or a piece of paper. Beta particles are electrons, and they can be stopped by an aluminum sheet a few millimeters thick. Gamma radiation consists of high-energy photons and has no mass or charge. It is the penetrating of the three and is stopped only by an appreciable amount of heavy metal radiation shielding (usually lead or barium based).

Radiochemistry also includes the study of the behavior of radioactive isotopes in the atmospheric environment. Collision of cosmic rays, mainly protons, with nuclei of nitrogen, oxygen, and argon in the upper atmosphere produces nucleons (protons and neutrons) and mesons. Secondary nuclear reactions between the produced nucleons and the atmospheric atoms are responsible for the formation of radioisotopes, such as ^{14}C through the reaction $^{14}\text{N}(\text{n}, \text{p})^{14}\text{C}$. The produced ^{14}C becomes incorporated into atmospheric carbon dioxide, resulting in uniform distribution in terrestrial biological body. The ^{14}C method is widely utilized as a dating method in archeology and anthropology. Other radioactive nuclides in the atmosphere, such as ^3H , ^7Be , ^{10}Be , ^{22}Na , ^{32}Si ,

^{32}P , ^{33}P , ^{35}S , and ^{36}Cl , are also derived from cosmic rays.

Definition

Radiogenic isotopes or radiogenic nuclides are produced by the decay of radioactive nuclei (e.g., ^{87}Sr

produced by the decay of ^{87}Rb). The abundances of radiogenic isotopes are commonly reported relative to that of a stable, non-radiogenic isotope of the same element (e.g., ^{86}Sr) as isotope ratios (e.g., $^{87}\text{Sr}/^{86}\text{Sr}$). In ► [geochronology](#), radiogenic isotopes are used for determining the timing and duration of geological events. They also provide tracers for chemical fractionations of parent and daughter elements by past geological processes, such as the chemical differentiation of the Earth.

Overview

Radiogenic isotopes are versatile tools in Earth sciences. In geochronology, they are used to determine the timescales of geological processes ranging from ages of individual minerals to the timescales of large-scale chemical differentiation of asteroids and terrestrial planets. As tracers of geological processes, radiogenic isotopes provide information on rates and pathways of geological processes, including the compositional evolution of the Earth and other planetary bodies, processes of planetary differentiation, as well as identifying the origin of Earth’s water.

Basic Methodology

Geochronology

Based on their half-lives, radioactive nuclides can be subdivided into long-lived nuclides with half-lives of more than ~ 100 Myr (e.g., $^{238}\text{U} \rightarrow ^{206}\text{Pb}$, ► [half-life](#) of 4.47×10^9 years) and short-lived or

extinct nuclides with half-lives of less than ~ 100 Myr (e.g., $^{26}\text{Al} \rightarrow ^{26}\text{Mg}$, half-life of 7.3×10^5 years) (Table 1). Owing to their short half-lives, short-lived nuclides only existed during the early stages of Solar System evolution and have since then decayed away (a ► [nuclide](#) is considered effectively extinct after about seven half-lives).

The basic equation for using long-lived decay systems in geochronology is

$$R = R_0 + R^{P/D} \times (e^{\lambda t} - 1) \tag{1}$$

where R is the ratio of the radiogenic isotope to a non-radiogenic isotope of the same element (e.g., $^{206}\text{Pb}/^{204}\text{Pb}$), R_0 is the initial ratio [$^{206}\text{Pb}/^{204}\text{Pb}$] $_0$, $R^{P/D}$ is the parent-to-daughter ratio at the present day (e.g., $^{238}\text{U}/^{204}\text{Pb}$), λ is the decay constant, and t is time running backward from present. R and $R^{P/D}$ of a sample can be directly measured for a sample, but the determination of the initial ratio R_0 is more difficult. However, Eq. 1 and Fig. 1 illustrate that in a plot of R versus $R^{P/D}$ cogenetic samples having the same age t and an initial isotopic composition R_0 plot on a straight line, termed an isochron. An age t can be determined from the slope of such an isochron, which is equivalent to $e^{\lambda t} - 1$.

Figure 1 shows an example of one of the first isochrons obtained for meteorites (Patterson 1956). Patterson observed that different groups of meteorites (open circles) have different Pb isotopic compositions that correlate with their U/Pb ratios. Recent oceanic sediments, which at the time of Patterson’s study were thought to

^{238}U	^{206}Pb	^{204}Pb	4.47×10^9	

Radiogenic Isotopes,

Fig. 1 $^{207}\text{Pb}/^{204}\text{Pb}$ versus $^{206}\text{Pb}/^{204}\text{Pb}$ isochron determined by Patterson (1956) for meteorites. Henbury and Canyon Diablo are iron meteorites, Forest City and Modoc chondrites, and Nuevo Laredo a basaltic meteorite

represent the Pb isotopic composition of the bulk silicate Earth, plot next the isochron defined by the meteorites. This led Patterson to conclude that the Earth and meteorites must have the same age and origin. However, subsequent work has shown that pelagic sediments only provide a rough approximation of the true composition of the bulk silicate Earth. The current best estimates for the Pb-Pb [age of the Earth](#) are younger but within experimental error of Patterson's original determination and range from ~ 4.52 to ~ 4.44 Ga (Allègre et al. 1995; Rudge et al. 2010; Wood and Halliday 2010).

The basic equation for using short-lived nuclides is.

$$R = R_0 + R_s^{P/D} \times P_0^{ij} \quad (2)$$

where $R_s^{P/D}$ is the parent-to-daughter ratio of two stable nuclides and P_0^{ij} is the initial abundance ratio of a short-lived nuclide. In case of the ^{26}Al - ^{26}Mg system, Eq. 2 reads:

$$\left(\frac{^{26}\text{Mg}}{^{24}\text{Mg}}\right)_0 = \left(\frac{^{26}\text{Mg}}{^{24}\text{Mg}}\right) + \left(\frac{^{27}\text{Al}}{^{24}\text{Mg}}\right) \times \left(\frac{^{26}\text{Al}}{^{27}\text{Al}}\right)_0 \quad (3)$$

In a plot of $^{26}\text{Mg}/^{24}\text{Mg}$ versus $^{27}\text{Al}/^{24}\text{Mg}$, cogenetic samples having the same initial Mg isotopic composition plot on an isochron whose slope corresponds to the initial $^{26}\text{Al}/^{27}\text{Al}$ of these samples. Figure 2 shows an example of an

^{26}Al - ^{26}Mg isochron for a Ca-Al-rich inclusion ([▶ CAIs](#)) from the carbonaceous [▶ chondrite](#) Allende. This isochron provided the first evidence that live ^{26}Al had existed in the Solar System and, since CAI are thought to be the first condensates of the solar nebula, shows that the initial $^{26}\text{Al}/^{27}\text{Al}$ of the Solar System was $\sim 5 \times 10^{-5}$ (Lee et al. 1977).

Since Eq. 2 does not contain the age t , short-lived nuclides cannot provide absolute ages. However, time differences Δt between any two samples 1 and 2 can be precisely determined from their initial abundance ratios P_0^{ij} . In case of the ^{26}Al - ^{26}Mg system, ages are usually given as the time elapsed since the formation of CAI and can be calculated as follows:

$$\Delta t = \frac{1}{\lambda} \times \ln \left[\frac{\left(\frac{^{26}\text{Al}}{^{27}\text{Al}}\right)_{\text{CAI}}}{\left(\frac{^{26}\text{Al}}{^{27}\text{Al}}\right)_{\text{sample}}} \right] \quad (4)$$

Similar equations apply to other short-lived systems and can be used to calculate time differences between any two samples or events.

Model Ages

A different type of age can be obtained from a single measurement of R and $R^{P/D}$ (for long-lived systems) or R and $R_s^{P/D}$ (for short-lived systems) combined with an assumption regarding the initial isotopic composition of the daughter, R_0 . This approach requires a model of the isotopic evolution of the reservoir a sample is derived from, such

Radiogenic Isotopes,

Fig. 2 $^{26}\text{Mg}/^{24}\text{Mg}$ versus $^{27}\text{Al}/^{24}\text{Mg}$ isochron for the Allende CAI WA as determined by Lee et al. (1977). Anorthites from this CAI contain highly radiogenic Mg, providing the first evidence for live ^{26}Al in the early solar system

that these ages are referred to as model ages. A prominent example is model ages calculated relative to a Chondritic Uniform Reservoir (CHUR), a term introduced by DePaolo and Wasserburg (1976) to investigate mantle-crust differentiation in the Earth using the ^{147}Sm - ^{143}Nd chronometer. The underlying assumption of the CHUR model is that the parent-to-daughter ratio of an isotope system in the bulk Earth is chondritic. Since both Sm and Nd are refractory elements, this is a reasonable assumption. This assumption also holds for the Lu-Hf and Hf-W systems, as all these elements are refractory.

Figure 3 illustrates the concept of CHUR model ages for the ^{176}Lu - ^{176}Hf system. The Earth's crust is thought to have formed by partial melting of the ► mantle. During melting, Hf enters the melt more readily than Lu, such that the crust will evolve with lower Lu/Hf than the bulk Earth, whereas the Lu/Hf of the depleted mantle will be higher. Over time, the $^{176}\text{Hf}/^{177}\text{Hf}$ ratios of crust and mantle diverge to lower and higher values compared to the evolution of CHUR, respectively. By convention, Hf isotope ratios are expressed in $\varepsilon_{\text{Hf}}(t)$ as deviations in parts per 10^4 from the Hf isotopic composition of CHUR. Mantle-derived rocks are thus characterized by positive $\varepsilon_{\text{Hf}}(t)$ and crustal rocks by negative $\varepsilon_{\text{Hf}}(t)$ values.

Assuming that the mantle has the same Lu-Hf isotopic history as CHUR, the model time of crust formation can be determined from Lu-Hf data by calculating the time at which the crust had the same Hf isotopic composition as CHUR. In case

of the ^{176}Lu - ^{176}Hf system, such a model age is calculated as follows:

$$\tau_{\text{CHUR}} = \frac{1}{\lambda} \ln \left(\frac{\left(\frac{^{176}\text{Hf}}{^{177}\text{Hf}} \right)_{\text{sample}} - \left(\frac{^{176}\text{Hf}}{^{177}\text{Hf}} \right)_{\text{CHUR}}}{\left(\frac{^{176}\text{Lu}}{^{177}\text{Hf}} \right)_{\text{sample}} - \left(\frac{^{176}\text{Lu}}{^{177}\text{Hf}} \right)_{\text{CHUR}}} + 1 \right) \quad (5)$$

CHUR model ages are mostly used in studies investigating the large-scale geological evolution of planetary bodies, such as mantle-crust differentiation (^{147}Sm - ^{143}Nd , ^{176}Lu - ^{176}Hf) and core formation (^{182}Hf - ^{182}W).

Key Research Findings

Dating Meteorites and the Beginning of Planet Formation

Chondrites are a group of meteorites that never melted and preserved information on processes operating in the solar nebula, i.e., in the protoplanetary disk orbiting the young Sun. Many chondrites contain Ca-Al-rich inclusions (CAI), which consist of those minerals predicted to be the first condensates from a solar gas. Owing to their high U/Pb ratios, the age of CAI can be determined precisely by U-Pb chronometry and is ~ 4.567 Ga. Since CAI are the oldest objects known to have formed in the Solar System, their age is commonly used to define the age of the Solar System (Amelin et al. 2002, 2010).

^{26}Al - ^{26}Mg data for ► chondrules, the major component of most chondrites, show that they

Radiogenic Isotopes, Fig. 3 Hf isotopic composition of Archean and Hadean zircons. Zircons have high Hf contents but contain almost no Lu, such that they can be used to measure the Hf isotopic composition at the time of their crystallization. The latter can readily be determined using

the U-Pb system. This makes zircons both a powerful dating tool and a powerful monitor of crustal growth. Measurable Hf isotopic variations already existed at ~ 4.3 Ga, implying that substantial crust had already formed by this time. (Redrawn from Scherer et al. 2007)

have much lower initial $^{26}\text{Al}/^{27}\text{Al}$ ratios than CAI. Provided that ^{26}Al was homogeneously distributed within the region where CAI and chondrules formed, the differences in initial $^{26}\text{Al}/^{27}\text{Al}$ ratios indicate that most chondrules formed ~ 2 Ma after CAI. Chondrules from some chondrites appear to have formed even later, some as late as 4–5 Ma after CAI formation. As chondrules formed by rapid melting of dust aggregates in the solar nebula, the chondrite parent bodies must thus have accreted several million years after Solar System formation (e.g., Krot et al. 2009).

Iron meteorites are thought to derive from the metal cores of differentiated protoplanets. The timing of their formation can be determined using the ^{182}Hf - ^{182}W chronometer (e.g., Kleine et al. 2009). Both Hf and W are refractory and thus assumed to occur in chondritic relative abundances in bulk planetary bodies (see above). During core formation, lithophile Hf remains in the mantle while siderophile W preferentially partitions into the core, resulting in high Hf/W ratios in the mantle and a low Hf/W ratio of ~ 0 in the core. Consequently, over time the mantle will evolve to higher-than-chondritic $^{182}\text{W}/^{184}\text{W}$ ratios, while the core maintains its W isotopic composition

acquired at the time of core formation (Fig. 4). The magnitude of the W isotopic effects in the mantle or core relative to chondrites can thus be used to determine an age of core formation in a way similar to that described above for Lu-Hf CHUR model ages (Fig. 4). The Hf-W data for magmatic iron meteorites show that these bodies underwent melting and core formation within less than ~ 1 Myr after CAI formation and, hence, well before the chondrite parent bodies accreted. Melting in the iron meteorite parent bodies most likely was triggered by energy release from ^{26}Al decay, while the chondrite parent bodies remained undifferentiated because they contained too little ^{26}Al to melt, probably because they accreted late (Kleine et al. 2009).

Accretion of the Earth and Segregation of Its Core

Accretion of the Earth involved highly energetic collisions with ► Moon- to Mars-sized planetary embryos, which raised the temperature of the Earth by thousands of degrees, causing the formation of magma oceans in which metal could separate from molten silicate and segregate toward to the center, forming a core (Stevenson 2008).

Radiogenic Isotopes, Fig. 4 W isotopic evolution in a planetary body undergoing core formation. By convention, the $^{182}\text{W}/^{184}\text{W}$ ratios are given in $\epsilon^{182}\text{W}$, which are the parts per 10^4 deviation of the $^{182}\text{W}/^{184}\text{W}$ of a sample from that of the terrestrial standard. Chondrites are characterized by an $\epsilon^{182}\text{W}$ value of -1.9 , whereas early formed metals (such as iron meteorites) have $\epsilon^{182}\text{W}$ values of around -3.3 . The W isotopic evolution of CHUR represents that of the bulk undifferentiated planet. During core formation,

the chondritic Hf/W of the bulk planet is fractionated between mantle and core. The mantle has high Hf/W and evolves to radiogenic $\epsilon^{182}\text{W}$, while the core contains virtually no Hf such that its $\epsilon^{182}\text{W}$ remains constant over time. By comparing $\epsilon^{182}\text{W}$ and Hf/W of the mantle or core to that of chondrites, a model time of core formation can be calculated. The bulk silicate Earth has an $\epsilon^{182}\text{W}$ value of 0, corresponding to a two-stage model time of core formation of ~ 30 Myr after CAI formation

Thus, the rate of Earth's accretion can be determined by dating core formation. Such age constraints can be obtained from the U-Pb and Hf-W decay systems.

All estimates for the Pb isotopic composition of the **bulk silicate Earth** (BSE) plot to the right of the Geochron (i.e., the line of “zero” age for U/Pb fractionation) in a diagram of $^{207}\text{Pb}/^{204}\text{Pb}$ versus $^{206}\text{Pb}/^{204}\text{Pb}$, indicating an early loss of Pb from Earth's mantle (Fig. 5). Under the elevated pressure and temperature conditions of Earth's core formation, Pb is siderophile such that Pb loss most probably was to the Earth's core (Allègre et al. 1995; Wood and Halliday 2010). Estimates of the U-Pb model age of the Earth range between 56 and 130 Myr after Solar System formation (i.e., 4.52–4.44 Ga) and correspond to the time when Earth's core was fully formed and, hence, Earth entirely accreted (Rudge et al. 2010). The range in ages reflects uncertainties in the Pb isotopic composition of the BSE and bulk Earth as well as in the U/Pb ratio of the bulk Earth.

The BSE has a higher $^{182}\text{W}/^{184}\text{W}$ ratio ($\epsilon^{182}\text{W} = 0$) than the undifferentiated chondritic

meteorites ($\epsilon^{182}\text{W} = -1.9$), indicating that some fraction of Earth's core formed during the lifetime of ^{182}Hf . Assuming that core formation took place as a single event from a fully formed Earth, the W isotopic composition of Earth's mantle corresponds to a CHUR model age of ~ 30 Myr after CAI formation. However, Earth's core formed continuously during accretion over several millions of years, indicating that the W isotopic composition of Earth's mantle does not simply reflect one single event of core formation. Assuming that the Earth accreted at an exponentially decreasing rate (Wetherill 1986) and that the core formed in equilibrium with the mantle, the mean life of accretion τ of the Earth is ~ 11 Myr (corresponding to the time at which 63% of Earth's mass had accreted), while the end of accretion is given by the two-stage model age of ~ 30 Myr after Solar System formation (Jacobsen 2005). These timescales are faster than those obtained from U-Pb using the same model however (Halliday 2008; Kleine et al. 2009). The Hf-W and U-Pb timescales can be matched by assuming either disequilibrium during core formation or a rapid early accretion of the Earth

Radiogenic Isotopes, Fig. 5 Pb isotopic systematics of the bulk silicate Earth. Different estimates for the Pb isotopic composition of the BSE are shown as blue circles (for references see Rudge et al. 2010). The blue line labeled “Geochron” is the line of zero age U/Pb fractionation at the beginning of the Solar System. The red line represents the Pb isotopic compositions for which the timing of U/Pb fractionation would be consistent with that of Hf-W

fractionation in the exponential model. The black lines represent isochrons calculated with U/Pb fractionations during core formation at 50, 100, and 150 Myr after the beginning of the Solar System. The Pb isotopic composition of the BSE implies U/Pb fractionation due to core formation some time between ~50 and ~150 Myr after CAI formation

followed by a long accretion hiatus and a late Moon-forming impact (Halliday 2008; Rudge et al. 2010). Figure 6 illustrates these two end-member models for Earth’s accretion and differentiation.

Age and Origin of the Moon

The Moon formed at the very end of Earth’s accretion when a Mars-sized body (sometimes termed Theia) collided with the proto-Earth (Hartmann and Davis 1975; Canup and Asphaug 2001). As a result of the large amount of energy released during this collision, the Moon melted to form a magma ocean. The timescales for the formation of the Moon and solidification of its magma ocean can be quantified using the ^{182}Hf - ^{182}W , ^{146}Sm - ^{142}Nd , and ^{176}Lu - ^{176}Hf systems. Application of Hf-W chronometry to date, the Moon has been hampered by the cosmic-ray-induced production of ^{182}W by neutron capture of ^{181}Ta , resulting in apparent Hf-W ages of the Moon that are too old. However, the analyses of lunar metals that do not contain any Ta and hence Ta-derived ^{182}W show that in spite of large Hf/W fractionations within the silicate Moon, all lunar

samples have indistinguishable $^{182}\text{W}/^{184}\text{W}$ ratios, demonstrating that the lunar mantle must have solidified later than 60 Myr after Solar System formation (Touboul et al. 2007). The Lu-Hf and U-Pb systematics of KREEP, the residual liquid of the magma ocean, indicate that the magma ocean was completely solidified by ~4.4 Ga (Taylor et al. 2009; Nemchin et al. 2009), consistent with the Hf-W results but more difficult to reconcile with a ~4.3 Ga ^{146}Sm - ^{142}Nd model age of the lunar mantle.

The identical W isotopic compositions of the silicate Earth and Moon combined with their different Hf/W ratios provide evidence that the Earth and Moon separated late in accretion history, probably later than ~50 Ma after Solar System formation (Touboul et al. 2007). ^{147}Sm - ^{143}Nd chronometry indicates that the oldest lunar rocks, the ferroan anorthosites, crystallized no later than ~150 Ma following Solar System formation (Norman et al. 2003), such that the Moon most probably formed between 50 and 150 Ma after CAI formation, at about the same time than given by the U-Pb age of the Earth and the age of Pb loss from the Moon.

Radiogenic Isotopes, Fig. 6 Two end-member models of Earth's accretion and core formation based on Hf-W and U-Pb data. (a, b) Disequilibrium core formation: only 40% of the metal cores of newly accreted bodies are assumed to have first equilibrated with Earth's mantle before entering Earth's core. (c, d) Equilibrium core formation: for full equilibration during core formation, the main mass of the

Earth must have accreted rapidly, followed by a long accretion hiatus before a final Moon-forming impact at ~ 100 Myr. Both models can satisfy the Hf-W and U-Pb observations and indicate that Earth's accretion terminated late, some 100 Myr after Solar System formation (After Halliday 2008; Kleine et al. 2009; Rudge et al. 2010)

Origin of Earth's Water and the Late Veneer

Radiogenic isotopes can provide some information on the origin of Earth's water. The terrestrial mantle contains higher abundances of the platinum group elements (PGE) than expected from metal-silicate partitioning under equilibrium conditions. The overabundance of the PGEs has been interpreted to reflect the addition of a late chondritic veneer to Earth's mantle after formation of its core. Rhenium-187 decays to ^{187}Os such that the $^{187}\text{Os}/^{188}\text{Os}$ ratio of Earth's mantle precisely constrains the time-averaged Re/Os ratio of Earth's mantle. Osmium isotope data for terrestrial rocks and chondrites indicate that the Re/Os ratio of Earth's mantle is similar to ordinary chondrites but different from ► carbonaceous

chondrites. Consequently, the ► late veneer is thought to have had a composition similar to that of ordinary chondrites (Walker 2009), but these contain too little water to be the main source of Earth's water. This has led to the view that Earth received substantial quantities of water during its accretion (Drake and Righter 2002).

Early Differentiation and Mantle-Crust Evolution in the Earth

The decay products of long-lived radionuclides provide fundamental information regarding the composition, structure, and evolutionary history of the Earth's crust and mantle (Hofmann 1997). Among these, the ^{147}Sm - ^{143}Nd system has widely been used to investigate the early differentiation

of the Earth, but because Earth's oldest rocks postdate its accretion by several hundred of millions of years, the ^{147}Sm - ^{143}Nd constraints on Earth's earliest differentiation remain imprecise. Evidence for very early differentiation of Earth's mantle comes from Archean and Hadean zircons, some of which crystallized as early as 4.0–4.4 Ga ago. The ^{176}Lu - ^{176}Hf systematics of these zircons indicate that substantial crust on the Earth had already formed by ~ 4.3 Ga (Harrison et al. 2005; Scherer et al. 2007) (Fig. 3).

Short-lived nuclides can potentially provide more precise constraints on the timing of Earth's earliest differentiation because variation in their daughter products can only be produced during the first few hundred of millions of years of the Solar System. Relative to Earth's mantle, some Archean rocks from the Isua supercrustal belt have small ^{142}Nd excesses, indicating that an early proto-crust had already formed at 4.44 ± 0.08 Ga (Caro et al. 2003), that is, very soon after Earth had fully accreted.

The terrestrial mantle exhibits a small ^{142}Nd excess (from the decay of ^{146}Sm) relative to chondritic meteorites, which was interpreted to reflect depletion of the mantle within the first 30 Myr of the Solar System. A complementary early enriched reservoir may be hidden at the core-mantle boundary (Chase and Patchett 1988; Boyet and Carlson 2005). The preservation of a signature of such an early differentiation of the terrestrial mantle is difficult to reconcile with the age of the Earth's core and the age of the Moon however. The ^{142}Nd excess of the terrestrial mantle may thus reflect a slightly higher-than-chondritic Sm/Nd ratio of the Earth (Caro et al. 2008; Kleine et al. 2009).

Radiolysis

Steven B. Charnley

Solar System Exploration Division, Code 691,
Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

Radiolysis refers to the dissociation of molecules by nuclear radiation (e.g., by alpha particles = helium nuclei).

In astrochemistry, radiolysis occurs in the gas phase by interaction with cosmic rays and in the solid phase through the impact of these cosmic rays with the grain materials, particularly the ice mantles.

Raman Scattering

Lisa Kaltenegger

Cornell University, Ithaca, NY, USA

Synonyms

- [Inelastic photon scattering](#)

Definition

Raman scattering is the inelastic scattering of a photon. Most photons are elastically scattered from atoms or molecules (► [Rayleigh scattering](#)), such that the scattered photons have the same energy and wavelength as the incident photons. However, a small fraction of scattered light is absorbed and subsequently emitted via an intermediate electronic state, with the scattered photons having a frequency different from the frequency of the incident photons. The energy differences are equal to the differences of the vibrational and rotational energy levels of the molecule. There are two types of Raman scattering: (1) Stokes scattering, when the molecule absorbs energy and the resulting photon has a lower energy and is shifted to the red side of the incident spectrum, and (2) anti-Stokes scattering, where the molecule loses energy and the resulting photons are more energetic and thus shifted to the blue side of the spectrum.

Raman Spectroscopy

Francis McCubbin
Institute of Meteoritics, University of New Mexico, Albuquerque, NM, USA

Definition

Raman spectroscopy is a vibrational spectroscopic technique that depends on the inelastic scattering of photons. It is useful for identifying the presence of specific molecular groups within a solid, liquid, or gaseous sample. Raman spectroscopy is widely considered to be a complementary technique to infrared spectroscopy (although Raman spectroscopy can be carried out at infrared wavelengths), but Raman spectroscopy is typically preferred in

studies of inorganic carbon. Specifically, Raman spectroscopy can be used to detect double- and triple-bonded carbon groups, which are invisible to standard infrared spectroscopic techniques. The ability to detect carbon-bearing molecules, coupled with the submicron spatial resolution of modern Raman microspectroscopic imagers, makes Raman spectroscopy an important technique for studying microfossils. Furthermore, Raman spectroscopy is nondestructive, so it makes an excellent tool for classifying the mineralogy and microtextures of precious samples including meteorites and lunar samples returned from the Apollo and Luna missions to the Moon.

History

Raman spectroscopy is named after Sir Chandrasekhara Venkata Raman. Sir Raman discovered the phenomenon that bears his name in 1928 using sunlight (light source), a telescope (collector), and his eyes (detector). Today, Raman instruments are much more complex with lasers (light source), lenses, triple monochromators and holographic gratings (collector), and charge-coupled devices (detector).

Lanthanides; Rare earth metals; Rare earth oxides

Acronyms

REE

Definition

The rare earth elements (or REE) comprise the family of lanthanides (atomic number $Z = 57$ –71), corresponding to the progressive filling of the 4f orbitals, together with the elements scandium (Sc, $Z = 21$) and yttrium (Y, $z = 39$) (Table 1). Their abundance in geological materials is usually less than 0.1 wt. %, that is, the term “rare” compared to abundances of rock-composing major oxides (SiO_2 , K_2O , CaCO_3 , etc.). They are an extremely consistent group in terms of chemical behavior, making them suitable tracers of numerous geological processes. Rare earth elements are considered particularly informative on the conditions prevailing during the

formation of rocks, and REE studies have important applications in petrology and in oceanography, where these elements are derived from the weathering of continental masses and ► [mid-ocean ridges](#) hydrothermalism.

Overview

The term “rare earth elements” derives from minerals from which they were first isolated, which were uncommon oxide-type minerals. However, this name is no longer accepted by the IUPAC (International Union of Pure and Applied Chemistry) because some of these elements are neither “rare” nor “earths” (an obsolete term for water-insoluble strong-basic oxides of electropositive metals). The low atomic number elements of the REE series are termed light rare earth elements (abbreviated LREE: from lanthanum (La) to neodymium (Nd); $Z = 57$ –60), and those with the higher atomic number are referred to as heavy rare earth elements (abbreviated HREE, from gadolinium (Gd) to lutetium (Lu); $Z = 64$ –71). Sometimes the term middle rare earth elements (abbreviated MREE), is loosely applied to the

Rare Earth Elements, Table 1 List of lanthanides + Sc and Y. Ionic radius is for trivalent ionic species (coordination number = 8) unless indicated (from Rollinson 1993 modified)

Atomic number	Name	Symbol	Group	Ionic radius (pm)*
57	Lanthanum	La	LREE	116
58	Cerium	Ce	LREE	114.3 (97, Ce^{3+})
59	Praseodymium	Pr	LREE	112.6
60	Neodymium	Nd	LREE	110.9
61	Promethium	Pm	MREE	Not naturally occurring
62	Samarium	Sm	MREE	107.9
63	Europium	Eu	MREE	106.6, 125 (Eu^{2+})
64	Gadolinium	Gd	MREE, HREE	105.3
65	Terbium	Tb	MREE, HREE	104.0
66	Dysprosium	Dy	MREE, HREE	102.7
67	Holmium	Ho	MREE, HREE	101.5
68	Erbium	Er	HREE	100.4
69	Thulium	Tm	HREE	99.4
70	Ytterbium	Yb	HREE	98.5
71	Lutetium	Lu	HREE	97.7
68	Erbium	Er	HREE	100.4
21	Scandium	Sc	–	114
39	Yttrium	Y	–	101.9

elements from about promethium (Pm) to about holmium (Ho) ($Z = 61\text{--}63$). Promethium ($Z = 61$) is a short-lived nuclide and is not observed in nature.

Due to similar outer electron shells, REE have very similar chemical and physical properties. Yttrium (Y) mimics the heavy lanthanides, particularly Ho, because having a similar the ionic radii. However, scandium (Sc) is a substantially smaller cation with geochemical behavior that differs from other rare earths. In most literature, REE include only lanthanides and Y, and Sc is treated separately (Nozaki 2001). They behave generally as incompatible elements (elements that prefer to stay in residual melt liquid during fractional crystallization) and thus they tend to be “concentrated” in the terrestrial crusts. They all form stable valences of 3^+ ions with similar ionic radii, with exception of cerium (Ce) (which has valence 3^+ and 4^+) and europium (Eu) (which has valence 2^+ and 3^+). The chemical behavior of trivalent REE varies with decreasing ionic radius and increasing atomic number (*lanthanide contraction* effect). These smooth changes cause fractionation of REE during igneous and sedimentary processes. Rare earth elements are also quite insoluble and therefore relatively immobile during low-grade [▶ metamorphism](#), [▶ weathering](#), and [▶ hydrothermal alteration](#). This is a very important feature giving insight into the origin of [▶ igneous rocks](#) and [▶ sedimentary rocks](#) through the low-temperature processes that commonly affected the Archean crust. Eu^{2+} is more soluble than trivalent elements and Eu excess may indicate hydrothermal alteration. Cerium becomes tetravalent under marine oxidative conditions: Modern manganese (Mn) nodules show Ce excesses that are mirrored by the striking negative Ce anomaly of seawater (e.g., Nozaki 2001).

Basic Methodology

Rare earth elements are present in any geological material, rocks, minerals, and in aqueous fluids (Henderson 1984; Rollinson 1993; Nozaki 2001) and thus they can be used for tracing numerous

processes, from mantle differentiation (e.g., Weyer et al. 2003) to metasomatism (i.e., the chemical alteration of a rock by hydrothermal or metamorphic-related fluids) (e.g., Whitney and Olmsted 1998), from identifying redox reactions to trace sources of continental inputs in oceans (e.g., Nozaki 2001).

REE were initially measured by neutron-activation techniques, which have been progressively abandoned with the development of the thermal ionization mass spectrometry (TIMS) or inductively coupled plasma mass spectrometry (ICP-MS). Now this instrumentation is usually employed by laboratories worldwide to measure REE in rocks, minerals, or aqueous fluids at parts per million (ppm) to parts per billion (ppb) levels.

In order to smooth the natural variations inherited from nucleosynthesis, the abundances of REE are usually represented in the Coryell-Masuda diagram, often nicknamed “spider diagrams” (a term still popular but which is progressively changed into “multielement diagrams”), where REE are plotted alone or in combination with major and minor elements, along the x -axis (i.e., Fig. 1). The element abundances are first normalized to their concentrations in a specific reference material or in a particular geochemical reservoir and the normalized abundance plotted in the y -axis at log scale.

For igneous rocks, typical references include the composition estimated for the primitive mantle (i.e., the mantle prior to the extraction of the [▶ continental crust](#); Wood et al. 1979) or CI-chondrites, both synonymous of the Bulk Silicate Earth composition for most elements. Normalizing the rocks’ REE compositions to these references allows identifying anomalies in REE that can be related to processes of partial melting, differentiation, and fractional crystallization. For sediments, the references are the NASC (North American Shale Composite; Gromet et al. 1984) and the Post-Archean Average Australian Shale (PAAS; Taylor and McLennan 1985; McLennan 2001). The use of Precambrian shales as a reference allows to observe changes in REE composition with progressive continental growth, weathering, and recycling during eons.

Rare Earth Elements,

Fig. 1 Multielement diagram depicting major, trace, and REE elements in a typical ocean island basalt (OIB) and a mid-ocean ridge basalt (MORB) (from Winter 2001; redrawn). Concentrations are normalized against the chondritic values of Nakamura (1974). MORBs show strong depletion of most incompatible elements against an enrichment of the same elements for OIBs

Key Research Findings

Rare earth elements are used in a multitude of studies involving the evolution of the geosphere and hydrosphere and enumerating them are well beyond the scope of this entry. A few examples of applications related to the understanding of the Earth's origin are described below.

Applications

Igneous Petrology and the Archean Mantle

The REE concentration in igneous rocks is controlled by crystal-melt equilibria during magmatic evolution (=differentiation). During magmatic differentiation, elements termed *compatible* remain in minerals, while the residual liquid phase is enriched in *incompatible* elements. The LREE are very incompatible, whereas the HREE are only weakly incompatible, leading to the fractionation of the LREE/HREE ratio of rocks. In addition to the magmatic effects, depletion or enrichment of LREE is controlled by the REE chemistry of the source of the magmas. The upper mantle from which the continental crust has been extracted over the Earth's history is depleted in incompatible elements and thus in REE. Figure 1 shows the concentrations of sixteen REE normalized to the composition of chondrites and arranged in the order of increasing

compatibility for ocean island basalts (OIBs) and mid-ocean ridge basalts (MORBs). OIBs and MORBs show two distinct patterns (Fig. 1). MORBs are the product of large degrees of partial melting of the upper mantle, and thus MORB have comparable relative REE abundances to their mantle source (Gast 1968). In contrast, oceanic island basalts (OIBs) show extreme degrees of incompatible element enrichment. This has been attributed to lower degrees of partial melting of a less depleted source in incompatible elements than the MORB source.

Comparing modern and Archean REE patterns of igneous rocks can be useful for explaining the thermal evolution of the mantle. Arndt et al. (1997) compared Archean basalts and modern MORBs. Archean basalts show a stronger depletion in incompatible elements with respect to modern MORBs, which cannot be explained by variations in the composition of the mantle source (Fig. 2). As incompatible elements are diluted upon progressing melting, the weak enrichment of incompatible element in Archean basalts reveals extensive melting of the hotter Archean mantle.

Sedimentary Petrology and Archean Sediments

Different factors control the distribution of the REE in sedimentary rocks, depending on their origin as "clastic" sediments (which means derived

Rare Earth Elements,

Fig. 2 Multielement diagram showing major, trace, and REE elements in Archean tholeiitic basalts and in modern MORB, normalized against primitive mantle. The relative depletion of elements in Archean counterparts of modern basalts can be explained by a larger degree of partial melting produced in a hotter Archean mantle (After Arndt et al. 1997; redrawn)

from erosion of igneous, metamorphic, or sedimentary rocks) or “chemical” sediments, that is, sediments formed by the precipitation of minerals from seawater or hydrothermal fluids. The most important factor contributing to the REE content in clastic sediments is their provenance (igneous, metamorphic, or sedimentary source). This is because REE are essentially insoluble and present in very low concentrations in seawater (Fig. 3a). The REE present in clastic sediments are therefore chiefly transported as particulate matter and reflect the chemistry of their source.

The REE amount in aqueous fluids is a function of the type of complexes that the REE may form, their residence time in the ocean, and the oxidizing potential of the water. In shale-normalized REE + Y diagrams, modern seawater is characterized by depleted LREE relative to mid and HREE resulting in positively sloped patterns, with a characteristic positive anomaly for yttrium (Y) and a negative anomaly for cerium (Ce) (Fig. 3a) (Alibo and Nozaki 1998). The Ce anomaly is expressed as Ce/Ce^* , where Ce^* is interpolated between the neighbouring elements La and Nd. Likewise, the Eu anomaly is expressed as Eu/Eu^* , where Eu^* is interpolated between the neighboring elements Sm and Gd. The Y anomalies are related to its higher capability to make soluble complexes with respect to the neighboring REE. The Ce anomaly reveals the oxidation of Ce^{3+} into Ce^{4+} , which is rapidly

scavenged by Mn-Fe oxides. Cerium anomalies in sediments and sedimentary rocks are thus useful proxies for the state of oxidation in the ocean and the atmosphere in the past. The progressive enrichment from the lighter to the heavier REE is believed to result from the increasing capacity to form soluble complexes with increasing atomic mass. Hydrothermal fluids originate in convection cells along mid-ocean ridges and back-arc spreading centers. Chondrite-normalized or shales-normalized REE + Y patterns show enrichment of LREE compared to mid- and heavy REE and a pronounced positive Eu anomaly (Fig. 3a) (Michard et al. 1983; Douville et al. 1999; Bau and Dulski 1999). The Eu and LREE enrichment seem to be controlled by fluid-solid exchange with plagioclase (a reservoir of Eu).

These characteristics have been applied to interpret the REE patterns in Archean chemical sediments, mainly cherts (e.g., Bolhar et al. 2005; Orberger et al. 2006), banded iron formations (Bolhar et al. 2004, 2005), and stromatolitic carbonates (Kamber and Webb 2001; Van Kranendonk et al. 2003). Figure 3b shows the REE + Y pattern, in 3.5-Ga-old stromatolites from Strelley Pool, Pilbara Craton, in 2.5-Ga-old microbialites (a generic term referring to organo-sedimentary structures such as stromatolites) from the ► [Campbellrand-Malmani platform](#), South Africa, and in the 3.7 Ga-iron formations from ► [Isua](#), West Greenland. These

Rare Earth Elements, Fig. 3 Multielement diagram showing: (a) REE measured in seawater (data from Alibo and Nozaki 1998); anoxic water of the Saanich Inlet, BC, Canada, as analogue of anoxic Archean seawater (data from German and Elderfield 1989); and high-temperature hydrothermal vents (data from Bau and Dulski 1999). (b) Multielement diagram showing REE measured in chemical sediments: stromatolites from Strelley Pool, Pilbara Craton, Western Australia (data from Van

Kranendonk et al. 2003); iron formations from Isua Supracrustal Belt, West Greenland (data from Bolhar et al. 2004); and carbonate microbialites from the Campbellrand-Malmani platform, South Africa (data from Kamber and Webb 2001). REE concentrations are normalized against the new reference material Mud of Queensland of Kamber et al. (2005) based on analyses of 30 alluvial sediments collected from 25 rivers in Queensland, Eastern Australia

patterns differ from both modern seawater and hydrothermal solutions. Figure 3a suggests that these organisms may have grown in anoxic waters, such as those from the modern Saanich fjord behind the Vancouver Island, and attests to the prevailing low levels of free oxygen in the mid-Archean atmosphere.

In contrast, the direct influence of hydrothermal fluids can be observed in some Archean cherts (Fig. 4), which show REE patterns very similar to those measured in black-smoker hydrothermal fluids. This reflects the common interpretation of Archean cherts as a product of secondary silicification of meta- or volcanoclastic sediments by silica-rich hot fluids (e.g., Weis and Wasserburg 1987; Orberger et al. 2006).

Element/element diagrams can also be useful to determine the depositional environment of the Archean sediments, both in terms of source(s) and redox conditions, particularly looking at the Ce and Eu anomalies. This is particularly useful in sediments where isotopic biosignatures are measured, such as carbon or nitrogen isotopes (e.g., Pinti et al. 2009a) in order to determine if the

depositional environment is compatible with the habitats where past organisms lived and left isotopic traces of their metabolic activity.

Figure 5 illustrates the redox-sensitive Eu anomalies plotted against the Y/Ho ratios for Archean cherts sampled in 3.5 Ga formations of the North Pole dome (Pi-47-00, Pi-85-00, and Pano D136-0), famous Apex chert microfossil locality (sample Pi-02-07), stromatolite (Pi-02-47), and 3.2 Ga formations of Dixon Island (Pi-01-45), all located within the Archean Pilbara Greenstone Belt, Western Australia. Three fields are reported which correspond to the REE signatures of the three types of cherts which eventually existed during Precambrian (van den Boorn et al. 2007): (1) silicification of volcanoclastic debris by silica-saturated seawater and relatively weak or no hydrothermal input (S-cherts); and (2 and 3) in sediment-starved shallow or deep environments, interaction between hot Si-rich fluid and seawater in different proportions promoting orthochemical deposition of silica (C-cherts). These fields fall close to three possible sources of REE, corresponding to three distinct geological

Rare Earth Elements,

Fig. 4 Multielement diagram showing REE measured in high-temperature hydrothermal vents (data from Bau and Dulski 1999) and a 3.5 Ga Archean chert from radiating swarm dykes of the Dresser Formation, North Pole Dome, Western Australia (data from Orberger et al. 2006). Similarities between the fractionation of REE suggest the precipitation of chert (silicification) from hydrothermal fluids

**Rare Earth Elements,**

Fig. 5 Eu/Eu^* ratio calculated as $\text{Eu}/[(0.67\text{Sm} + 0.33\text{Tb})]_{\text{MUQ}}$ against the raw Y/Ho ratio. The three shaded areas labeled “S-chert” and “C-chert” have been obtained by plotting REE data from van den Boorn et al. (2007). Black dots are 3.5–3.2 Ga-chert samples from Pinti et al. (2009a)

environments: (1) hydrothermal fluids ($\text{Eu}/\text{Eu}^* \gg 5$ and $\text{Y}/\text{Ho} = 32$; Mills and Elderfield 1995); (2) upper-crust rocks ($\text{Eu}/\text{Eu}^* = 0.95$ and chondritic $\text{Y}/\text{Ho} = 26$; Taylor and McLennan 1981); and (3) Archean seawater represented by Strelley Pool stromatolites ($\text{Eu}/\text{Eu}^* = 2.05$ and superchondritic $\text{Y}/\text{Ho} = 70.3$; Van Kranendonk et al. 2003).

The diagram below shows that the silicified stromatolite (sample Pi-02-47) has typical REE values from the Archean seawater, well distinguished from other chert samples. Apex chert

REE signatures indicate an influence from hydrothermal fluids, as suggested by Brasier et al. (2002) and Pinti et al. (2009b). More interestingly, cherts (Pi-47-00, Pano D-136-0) which contain nitrogen with a light isotopic composition ($\delta^{15}\text{N}$ of -5%) were interpreted by Pinti et al. (2001) to derive from the metabolic activity of chemolithoautotrophs organisms living in hydrothermal environments have REE composition closer to that of C-cherts formed under a stronger influence of hydrothermal effluents with contribution of crustal material (Fig. 5).

Future Directions

Numerous studies on meteorites and lunar samples used REE to trace and quantify secondary processes such as hydrothermal alteration or the rate of mantle melting and crustal evolution. The study of REE on Martian meteorites is important to understand the dynamics of crust formation on this planet (e.g., Nyquist et al. 2016). When samples from Mars can be returned to Earth, REE measurements will be fundamental to shed light on the igneous and sedimentary history of the Red Planet. REE measurements were also performed on the asteroidal material brought to Earth from Itokawa (Hayabusa 1 mission) (Ebihara et al. 2015) and similar studies will be performed on grains from Ryugu (Hayabusa 2 mission) actually under examination and Bennu (OSIRIS-REx mission) which will return on Earth in 2023, to decipher the geological history of these asteroids representing planetesimals.

Rate Equation Models

Eric Herbst

University of Virginia, Charlottesville, VA, USA

Definition

Rate equation models are chemical simulations in which the rate of change of the concentration of each molecule in the simulation is written in terms of the rates of formation and depletion. The integration of the coupled differential equations leads to the concentration of each species as a function

of time. Large numbers of chemical reactions, typically greater than 1000, are needed to simulate the chemistry of interstellar clouds in the gas and on the surfaces of dust particles.

Overview

Rate equation models consist of kinetic differential equations, which equate the time derivative of the concentration of each molecule in the model with the sum of their rates of gain and loss (Wakelam et al. 2010). The gain and loss terms can involve bimolecular collisions between species or can involve bombardment by photons and external cosmic rays leading to ionization and dissociation. As an example, consider a gas-phase process in which a molecule C is formed by a reaction between species A and B and destroyed by collision with species D and by photon bombardment. The kinetic differential equation for species C is then

$$d[C]/dt = k_{AB}[A][B] - k_{CD}[C][D] - k_{\text{phot}}[C],$$

where the brackets refer to concentration and each k is a rate coefficient (sometimes referred to as a rate constant in the chemical literature). If the model includes grain chemistry, an additional loss term involves accretion of species C onto the dust grains, while an additional gain involves desorption of C from the grain, both thermal and non-thermal. Rate coefficients, if measured or calculated, are often fit to expressions of the type $\alpha(T/300 \text{ K})^\beta \exp(-\gamma/T)$.

Rate equation models normally contain a large number of these differential equations, which can be integrated to obtain concentrations as functions of time despite the fact that they are strongly coupled with each other and are “stiff,” a term that refers to strongly differing reaction times. In the interstellar medium, the granular chemistry can include reactions that occur on the surface of bare silicate or carbonaceous grains, as well as reactions on and in ice mantles, which build up in cold clouds. In the simplest treatments, all ice molecules are treated in the same manner, whether or not they lie on the surface or in the bulk of the

mantle. More complex models differentiate between these two phases. Reactions on grain surfaces can occur via a variety of different mechanisms, including thermal diffusion of reactants on grain surfaces leading to collisions (Langmuir-Hinshelwood mechanism), collisions of a gas-phase species with a species adsorbed on a grain (Eley-Rideal mechanism), and nonthermal motion of a reactant often newly landing on a grain and leading to an enhanced collision rate with a surface species (hot-atom mechanism). Additional processes include adsorption, thermal desorption, and nonthermal desorption via photons, cosmic rays, and the exothermicity of surface reactions. Chemical processes in the bulk mantle are poorly understood.

Concentrations of species both in the gas and on grains are typically expressed with respect to the total amount of gaseous hydrogen, both atomic and molecular, and known as fractional abundances. Rate equations involving surface species can be poor representations of surface chemistry in the limit of small numbers of selected important molecules per grain, where stochastic methods involving the treatment of individual species are more accurate if more computationally expensive. Rate equations can be modified to be more accurate in this limit (Garrod et al. 2009).

Rayleigh Scattering

Emmanuel Marcq

LATMOS/IPSL, UVSQ Université Paris-Saclay,
Sorbonne Université, CNRS, Guyancourt, France

Keywords

Scattering (conservative, elastic) · Far field · Polarizing

Definition

Rayleigh scattering is an exact, analytical solution to the problem of radiation scattering in the limit of a vanishingly small scattering particle compared to the radiation wavelength. As such, it is valid for gaseous molecules at wavelengths used in planetary atmospheric studies, resulting in a polarized, conservative scattering increasing toward shorter wavelengths. It gives a characteristic bluish hue to the upper layers of clear atmospheres, has a major influence on planetary albedos (and thus radiative balance), and provides a lower bound on the probed altitude for transit spectroscopy.

Overview

Hypotheses

In Rayleigh scattering, the scattering particle is assumed to be a point-like, *induced* electrical dipole such as:

$$\vec{p} = \alpha(\omega)\varepsilon_0\vec{E} \quad (1)$$

where $\vec{E}$ is the oscillating electrical field (angular frequency ω) from the incident radiation, $\vec{p}$ the induced electrical dipole, ε_0 the vacuum permittivity, and $\alpha(\omega)$ the scalar *polarizability* of the induced dipole (dimensionnally homogeneous to a volume in SI units).

Since $\vec{E}$ oscillates at a frequency $\nu = \omega/2\pi$, then so does $\vec{p}$. Thus, like any variable electrical

dipole, the induced dipole will radiate its own electromagnetic radiation in all directions at the same frequency – as such, Rayleigh scattering is a typical example of *elastic scattering*.

The simplest model for the induced dipole is an electronic cloud subject to a harmonic potential around a positive nucleus. In such a case, there will be a phase shift between the electronic oscillation and the incident field, leading to partial absorption of the incident radiation. The absorbed power is exactly equal to that of the scattered radiation, so that no energy leaves the electromagnetic field. In other words, Rayleigh scattering is an example of *conservative scattering*: $\varpi_0 = 1$ at all frequencies.

Finally, three last hypotheses are assumed:

- Only *far field* scattered electromagnetic radiation is considered, that is, neglecting terms which vanish faster than r^{-2} , r being the distance between the observer and the scattering dipole.
- The incident radiation frequency ν is assumed to be much smaller than the resonant frequency ν_0 associated with the harmonic potential of the dipole: $\nu \ll \nu_0$.
- The medium is dilute, that is inter-dipoles interactions are negligible, which is the case in an ideal gaseous phase.

Cross Section

The scattering cross section in Rayleigh regime is given by:

$$\sigma_\lambda = \frac{128\pi^5\alpha_0^2}{3\lambda^4} \quad (2)$$

or, using macroscopic quantities such as (real) refractive index n and scatterers number density N instead of the microscopic static polarizability α_0 :

$$\sigma_\lambda = \frac{8\pi^3(n^2 - 1)^2}{3N^2\lambda^4}f(\delta) \quad (3)$$

The weak dependency of n with wavelength yields the characteristic spectral exponent $\sigma_\lambda \propto \lambda^{-4}$ of Rayleigh scattering, sometimes corrected as

$\sigma_\lambda \propto \lambda^{-4+\varepsilon}$ with $\varepsilon \ll 1$. Also, a corrective multiplicative factor $f(\delta) = \frac{6+3\delta}{6-7\delta} \approx 1$ for $\delta \ll 1$ is included in order to account for the anisotropy of molecular polarizability.

Phase Function

The scalar phase function of Rayleigh scattering only depends on the scattering angle Θ and is given by:

$$P(\Theta) = \frac{3}{4}(1 + \cos^2 \Theta) \quad (4)$$

yielding an asymmetry parameter $g = 0$, although Rayleigh scattering is *not* isotropic.

Polarization

In the single scattering limit, Rayleigh scattering is strongly polarizing, as can be seen in its phase matrix in the Stokes formalism (with the Q direction along the scattering plane):

$$\vec{P}(\Theta) = \frac{3}{4} \begin{pmatrix} \cos^2 \Theta + 1 & \cos^2 \Theta - 1 & 0 & 0 \\ \cos^2 \Theta - 1 & \cos^2 \Theta + 1 & 0 & 0 \\ 0 & 0 & 2 \cos \Theta & 0 \\ 0 & 0 & 0 & 2 \cos \Theta \end{pmatrix} \quad (5)$$

which yields the degree of linear polarization $P_l(\Theta)$ of (single) Rayleigh scattering for unpolarized incident radiation:

$$p_l(\Theta) = \frac{\sin^2 \Theta}{1 + \cos^2 \Theta} \quad (6)$$

P_l therefore ranges from 0 when source-scatterer-observer are aligned ($\Theta = 0^\circ$ or 180°), to 100% for $\Theta = 90^\circ$.

Importance in Planetary Atmospheres

Clear Sky

Out of gaseous absorption bands, radiative transfer within a purely gaseous atmosphere (with no aerosols) is well approximated by Rayleigh scattering in a gas layer of total optical depth $\tau \propto P$, yielding:

- A weakly attenuated direct beam, superimposed to a faint, blue, strongly polarized diffuse component for $\tau \ll 1$ (P less than ~ 0.1 bar, dominated by single scattering).

- A strongly attenuated reddened direct beam, superimposed to a bright, almost white, weakly polarized diffuse component for $\tau \gg 1$ (P larger than a few bars), due to the prevalence of multiple scattering in this case.

Transit Spectroscopy

Even in absence of clouds (or other aerosols) and gaseous absorption, Rayleigh scattering by clear atmospheres leads to the existence of a lower “transit floor,” limiting the atmospheric depth that can be probed using transit spectroscopy.

Due to the λ^{-4} dependency of Rayleigh scattering, this Rayleigh floor is more noticeable at shorter wavelengths and displays a characteristic spectral slope. It can be shown that:

$$\frac{d \ln \delta(\lambda)}{d \ln \lambda} \approx \frac{-8H}{R} \quad (7)$$

where $\delta(\lambda)$ is the transit depth for the considered wavelength, R the planetary radius, and H the atmospheric scale height. This provides a direct measurement of $H = kT/\mu g$, which can be used in turn to derive the atmospheric temperature T , local gravity acceleration g , or the mean molecular mass μ .

Albedo

Since Rayleigh scattering is conservative, it will always increase the albedo of a planet compared to the albedo of the underlying cloud ceiling or planetary surface. This effect is particularly dramatic:

- For thicker atmospheres ($P > 1$ bar)
- Around hotter stars, whose emission peak is shifted to shorter wavelengths
- For highly polarizable species, such as CO_2 , which exhibit a comparatively larger Rayleigh cross section

The case of CO_2 is of particular interest for planetary habitability, since it yields the classical definition of the *outer edge* of the habitable zone for typical telluric atmospheres (major species $\text{CO}_2\text{--H}_2\text{O--N}_2$). The amount of CO_2 greenhouse required to sustain surface temperatures above the freezing point of water increases with increasing

stellar distances. This leads to a higher albedo due the strong Rayleigh scattering by increasing CO₂, and therefore to a decrease of the equilibrium temperature that more than offsets the increase in greenhouse effect, hence the existence of an optimal distance that defines the outer edge of the habitable zone (Kasting et al. 1993; Neubauer et al. 2013).

Reaction Rate Coefficient

Steven B. Charnley
Solar System Exploration Division, Code 691,
Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

Reaction rate coefficients are the phenomenological coefficients occurring in rate expressions for

elementary chemical reactions. They can be determined either experimentally or theoretically. Bimolecular rate coefficients are expressed in units of cm³ s^{−1} and unimolecular ones in units of mol. s^{−1}. Typical values for interstellar chemistry are 10^{−9} cm³ s^{−1} for ion-neutral reactions and 10^{−11} cm³ s^{−1} for neutral-neutral reactions.

For example, for the reaction

where the letters represent either neutral or charged atoms or molecules, the rate at which the reaction occurs is $kn(A)n(B)$, with n the number density of a species in units of cm³ when the reaction rate coefficient k is expressed in cm³ s^{−1}.

Recombination

Enrique Viguera
Genetics Department Sciences Faculty,
University of Malaga, Malaga, Spain

Synonyms

[Crossing over](#); [DNA recombination](#)

Definition

Recombination is the process by which a new nucleic acid molecule formed by the combination (through covalent joining) of different sequences is obtained. It may involve (1) physical exchange between two duplex DNA homologous molecules

(homologous recombination) occurring at any point along their sequence, (2) the covalent joining of two molecules at specific sequences (site-specific recombination) or at unrelated sequences (nonhomologous end joining), and (3) the joining of two different parental sequences by short repeats during replication (copy-choice recombination). Recombination is a major source of genetic variation during meiosis (the process of reductional cellular division in which a diploid cell generates four haploid cells that results in the formation of gametes or spores) in eukaryotes, as well as in the reshuffling (process by which DNA or RNA chimeric forms are generated by a breakage-and-join or template-switching mechanisms) of immunoglobulin genes and viral genes. Recombination enzymes are implicated in ► [DNA repair](#).

Red Beds

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

Primary red beds are non-marine sedimentary sequences composed of sandstone, siltstone, or shale, covered by a red coating from the dehydration of goethite to hematite, the former being unstable at high temperatures and in the absence of water. These sedimentary rocks are deposited in hot arid climates (deserts) under oxidizing conditions. Red beds can form also during diagenesis (the processes after burial bringing to the lithification of sediments) by alteration of Mg-Fe-rich silicates by oxygenated groundwater. Red beds are common in the Proterozoic and Phanerozoic and mark particularly oxidizing periods such as during the Permian and the Triassic. Their absence in sedimentary sequences older than 2.65 Ga is often interpreted as an evidence of a poorly oxygenated atmosphere during the Archean.

Red Dwarf

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

The smallest ($M \sim 0.75\text{--}0.1\ M_{\odot}$), coolest ($T < 3,500\ \text{K}$), and least luminous ($L \sim 10^{-3}\text{--}0.1\ L_{\odot}$) fusion-powered stars, of spectral type M or late K, are called red dwarfs. They are the most numerous stars in the galaxy: 20 out of 30 stars in the solar neighborhood (including our nearest neighbor, Proxima Centauri) belong to this class. The less massive of them live up to 10^{13} years and all of them are still on the early main sequence phase. In many cases, planets have been found orbiting red dwarf stars.

Cross-References

Red Giant

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

A low or intermediate mass star ($0.4\text{--}8\ M$) in the late phase in its evolution becomes a red giant. After exhaustion of the central hydrogen fuel, the stellar core contracts, and the envelope expands (to tens or hundreds of times its size on the main sequence) and cools. Hydrogen fuses to helium in a shell surrounding the core, releasing more power (energy per unit time) than on the main sequence, and the point representing the star ascends the red giant branch of the ► [Hertzsprung-Russell diagram](#). The ascent stops when core temperature allows helium fusion, which takes place in the red clump (for metal-rich

stars) or in the ► [horizontal branch](#) (for metal-poor stars). More massive stars become red supergiants, which are substantially more luminous, while *red dwarfs* are fully convective and never evolve to red giants (no differentiation occurs between core and envelope).

Red Rectangle

Sun Kwok

Faculty of Science, The University of Hong Kong, Hong Kong, China

Keywords

Reflection nebulae · Extended red emission · Molecular synthesis – photoluminescence · Unidentified infrared emission bands

Synonyms

[AFGL 915](#), [IRAS 06176-1036](#); [HD 44179](#)

Definition

The Red Rectangle (astronomical coordinates J2000 RA = 06 19 58.2, DEC = $-10\ 38\ 14.7$) in the constellation Monoceros is the common name given to the infrared source CRL 915 (=AFGL 915). The central star of the nebula is HD 44179 = BD $-10^{\circ}1476$.

History

The Red Rectangle was discovered as the result of ground-based identification of infrared sources

observed in the Air Force Cambridge Research Laboratory (AFCRL) rocket sky survey. The infrared object AFCRL 915 coincides in position with a nebulous object on the National Geographic Society-Palomar Sky Survey red print. Because of the peculiar shape of the nebula, the object was given the name “the Red Rectangle” by Martin Cohen and Mike Merrill. In November 1973, Cohen and Merrill took a picture of the object with the 4-m telescope of the *Kitt Peak National Observatory* and found it to have a set of spikes in the form of an “X.” Nebular emission can be detected as far as 56 arc s from the star, giving a total angular extent of ~ 2 arc min in the sky. Recent *Hubble Space Telescope* imaging reveals a biconical structure, with the edges of the cone connected by straight “ladders” (see Fig. 1). These structures have been interpreted as the result of projection effects of concentric arcs due to spherical episodic outflows (Koning et al. 2011).

Overview

The central star HD 44179 is of ► [spectral type B9-A0](#) and has been identified as a spectroscopic binary system of period 319 ± 3 days (Van Winckel et al. 1995). It is deficient in iron ($[\text{Fe}/\text{H}] = -3.3$) and other refractory elements

(Mg, Si, Ca) but has normal solar C, N, O, S, abundances.

In the infrared, the Red Rectangle shows strong ► [unidentified infrared emission \(UIE\) bands](#) (Russell et al. 1978), suggesting that it is carbon rich. However, infrared emission features attributed to crystalline silicates (olivines) are also seen (Waters et al. 1998).

The astronomical extended red emission (ERE) was first discovered in the Red Rectangle (Schmidt et al. 1980). The ERE is likely to be due to photoluminescence of a carbonaceous semiconductor, but the exact chemical nature of the carrier is not known. Narrow emission features resembling those of the diffuse interstellar bands (DIB) can be seen on top of the continuum emission (Van Winckel et al. 2002).

Although the Red Rectangle is widely believed to be an object in the late stages of stellar evolution, its exact evolutionary status is not certain. The most interesting aspect is that the Red Rectangle is an active site of molecular synthesis. The fact that the DIB, ERE, and UIE unidentified emission phenomena all manifest themselves in this nebula raises the question of whether the carriers responsible for these three spectral mysteries are chemically related.

REDESPA

Jesús Martínez-Frías
Instituto de Geociencias, IGEO (CSIC-
Universidad Complutense de Madrid), Madrid,
Spain

Definition

REDESPA is the Spanish Planetology and Astrobiology Network (Red Española de Planetología y Astrobiología - REDESPA). It was founded and established by Dr. Jesús Martínez-Frías in 2013 under the umbrella of the Official Spanish Association of Geologists (ICOG). It is coordinated by a Board of more than 50 experts from different disciplines and from more than a dozen Spanish organizations including the Spanish National Research Council (CSIC), National Institute of Aerospace Technology (INTA), Centro de

Astrobiología (CAB), National Astronomic Observatory, and Science Museum of Castilla-La Mancha. REDESPA's mission is to promote planetary sciences and astrobiology as an open and versatile platform about different scientific subjects in a transdisciplinary approach, as well as educational, ethical, and societal issues. In the context of REDESPA, there is a special and specific chapter for young researchers (JIPA: Jóvenes Investigadores en Planetología y Astrobiología). The Membership registration in REDESPA is free and open to all interested people. REDESPA has developed different Courses, in collaboration with the ICOG's Professional School of Geology for Spain and LatinAmerica, about Planetology and Astrobiology (two editions), Mars and Catastrophes and Extinction Events and with the Ministry of Defense (Cátedra Juan de Borbón), Complutense University of Madrid and Institute of Geosciences (IGEO) about "Challenges in Astrobiology for the future of Humankind." REDESPA is one of the founding institutions of the Red Iberoamericana de Astrobiología (Latin American Astrobiology Network).

Redox Potential

Tori M. Hoehler
Exobiology Branch, NASA Ames Research
Center, Moffett Field, Mountain View, CA, USA

Keywords

Oxidation · Reduction · Electrochemical potential

Synonyms

E ; E_H ; Reduction potential

Definition

The redox potential is a measure of the thermodynamic driving force for a species to either donate

electrons (be oxidized) or accept electrons (be reduced) in aqueous chemical reactions.

Overview

With origins in electrochemistry, the concept of redox potential is also widely employed in describing and understanding the energetics of electron transfer chemistry in biological and geochemical systems. While defined in the strict chemical sense in reference to a single species or reaction, redox potential is also sometimes considered in both biology and geochemistry as a property of an overall system (e.g., an assemblage of microorganisms or minerals) that influences reactions and processes occurring within the system. Significant differences exist in the terminology and measures used to describe redox potential in the geochemical and biological sciences, but all relate fundamentally to the direction of, and thermodynamic driving force for, electron transfer in chemical reactions.

Electrochemistry

► **Reduction** or oxidation potentials came into use to describe, and are measured in, electrochemical cells. A chemically complete cell represents an oxidation half reaction (e.g., $X_{\text{red}} \rightarrow X_{\text{ox}} + ne^-$) coupled to a reduction half reaction (e.g., $Y_{\text{ox}} + ne^- \rightarrow Y_{\text{red}}$). The zero-current potential (in volts) is, in practice, measured for the entire cell ($X_{\text{red}} + Y_{\text{ox}} \rightarrow X_{\text{ox}} + Y_{\text{red}}$) but, in principle, constitutes a characteristic contribution from each half reaction. Reduction potentials can thus be measured (and are reported) relative to a reference standard half reaction, the standard hydrogen electrode (SHE), which is assigned a reduction potential of zero for all temperatures. The SHE consists of $\text{H}_2(\text{g})$ and $\text{H}^+(\text{aq})$ at unit fugacity (1 bar) and activity (1 M), respectively, with a platinum electrode. Tabulated data are typically presented for individual half reactions, as *standard* reduction potentials, E° (representing the characteristic contribution of that half reaction to an electrochemical cell with products and reactants in their standard state), at a specified temperature. A positive reduction potential implies that a given half reaction will proceed spontaneously

in the reductive direction when coupled to a half reaction having a less positive, or negative, reduction potential (in which case the second half reaction will proceed in the reverse direction, as an oxidation).

Electrochemical potential, E (or E_H , where the subscript H denotes reference to the SHE), is directly related to Gibbs energy change, ΔG , via the Nernst equation:

$$\Delta G = -nFE \quad (1)$$

where n is the stoichiometry of electron transfer in the reaction and F is the Faraday constant ($96,485 \text{ Coulombs} \cdot \text{mol}^{-1}$). Accordingly, E is sensitive to activities of products and reactants, as well as temperature and (to a significantly smaller degree, for aqueous reactions) pressure. The redox potential under nonstandard conditions is related to the standard reduction potential via

$$E = E^\circ - (RT/nF) \ln Q \quad (2)$$

where T is Kelvin temperature, R is the universal gas constant ($R = 8.314 \text{ J} \cdot \text{mol}^{-1} \text{ K}^{-1}$), and Q is the reaction quotient (the mathematical product of the activities of products raised to their respective stoichiometric coefficients divided by the mathematical product of the activities of reactants raised to their respective stoichiometric coefficients).

Biology

Virtually all reactions employed in catabolism, and many reactions employed in metabolism more generally, involve transfer of electrons. Extensive use is made of redox potentials in characterizing such processes. Because reactions in cell cytoplasm typically occur at near-neutral pH, a convention in biology is to work with a modified standard reduction potential, $E^{\circ'}$ (or E_o'), that specifies the zero-current potential for a given half reaction at pH = 7 (where standard reduction potential is expressed for unit H^+ activity, or pH = 0). For reactions that include protons as products or reactants, $E^{\circ'}$ differs from E° , but the two can be related through Eq. 2 above (by setting $\{\text{H}^+\} = 10^{-7}$ in the Q term). In both biology and geochemistry, the quantity $p\varepsilon$ is sometimes also used as a measure of redox

potential. In analogy to pH ($= -\log\{\text{H}^+\}$), $p\varepsilon$ is a measure of the solution activity of hypothetical free electrons, $p\varepsilon = -\log\{e^-\}$, and is related to E via

$$p\varepsilon = (F/2.3RT)E \quad (3)$$

Geochemistry

Geochemical systems are frequently also characterized with reference to redox potential. In addition to the measures above, the overall redox potential of a system may be described in terms of hypothetical activities or fugacities of H_2 or O_2 (e.g., a_{H_2} or f_{H_2}). Such expressions can be related to E via Eq. 2 above (by specifying the non-unit activity or fugacity of H_2 or O_2 in the reaction quotient (“ Q ”) term). Oxygen fugacity, f_{O_2} (and, therefore, redox potential), is sometimes also specified by reference to mineral “redox buffers.” These buffers, constituting the reduced and oxidized mineral species in a reaction involving oxygen, specify a unique f_{O_2} for a given set of physicochemical conditions. Thus, for example, “QFM” specifies f_{O_2} (for a given temperature) at equilibrium in the oxidation of fayalite (F) to magnetite (M) and quartz (Q), $3 \text{ Fe}_2\text{SiO}_4(\text{F}) + \text{O}_2 \rightarrow 2\text{Fe}_3\text{O}_4(\text{M}) + 3\text{SiO}_2(\text{Q})$, when all three mineral species are present. Mineral redox buffers are a convenient way to describe changing redox conditions over wide-ranging temperatures and to understand real-world effects on redox chemistry within the solid Earth.

Redox Zonation

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Keywords

Anoxic · Hypoxic · Oxic · Oxygen levels · Redox potential · Suboxic

Synonyms

Chemical zone; Metabolic zone; Redox zone

Definition

Redox zonation is the subdivision of natural environments based on the availability of O_2 to be consumed by biological respiration and inorganic chemical reactions. Traditional classification scheme for sedimentary environments in *oxic* and *anoxic* (with *anoxic*' sub-terms *sulfidic* and *nonsulfidic*) was based on the amount of measurable dissolved O_2 and dissolved sulfide in sediments at the time of precipitation of authigenic minerals (i.e., minerals grown in situ) (Berner 1981).

Overview

Redox zonation is common in natural systems, especially where mixing is limited, and oxygen is consumed by biological respiration and inorganic chemical reactions (Canfield and Thamdrup 2009).

Geochemical environments where sedimentary rocks formed are characterized in terms of hydrogen ion activity (pH) and the oxidation-reduction potential (Eh). But these parameters are not useful in a practical sense, pH being quite uniform for marine and nonmarine subaqueous sediments (pH = 6–8) and Eh not practically measurable (Berner 1981). Indeed, many of the species involved in sedimentary oxidation-reduction reactions, such as SO_4^{2-} or NH_4^+ , are not electroactive, that is, they do not readily accept or release electrons from the gold and platinum electrodes used for measuring the Eh. The common classification defined by Berner (1981) was based on the amount of dissolved O_2 and total sulfide (H_2S plus HS^-) measurable in a specific environment and the presence or absence of characteristic mineral phases sensitive to the occurrence of O_2 and H_2S in the environment.

The classification of redox zones in the sedimentary environment proposed by Berner in 1981 was subdivided into *oxic* and *anoxic* main zones depending upon the presence or absence of measurable dissolved oxygen. The *anoxic* zone was then further subdivided into *sulfidic* and *nonsulfidic* depending upon the presence or absence of measurable dissolved sulfide. Finally, *nonsulfidic* subzone was classified as post-oxic and methanic. Each zone and subzone was characterized by specific mineral phases stables at the O_2 and/or H_2S amount available in the environment.

In the classification of Berner (1981), the term *oxic* was then identified as a zone containing O_2 with concentrations higher than 1 $\mu\text{mol/L}$ and occurrence of ► [hematite](#), ► [goethite](#), manganese-bearing oxides but not of organic matter. The term *anoxic* was then assigned to a zone where O_2 concentration is less than 1 $\mu\text{mol/L}$. This *anoxic* zone was then subdivided into “sulfidic” (H_2S concentration higher than 1 $\mu\text{mol/L}$ and occurrence of pyrite, marcasite, and organic matter) and “non-sulfidic” (H_2S concentration less than 1 $\mu\text{mol/L}$). The “non-sulfidic” zone is in turn divided into two subzones. The first is termed *post-oxic* with presence of glauconite and iron silicates; no sulfide minerals and minor organic matter. The amount of organic matter is so small that decomposition cannot be run by sulfate

reduction but nitrate, manganese, and iron reduction (Berner 1981). The other subzone is *methanic*, a highly reducing anoxic-nonsulfidic environment with presence of siderite, sulfide minerals, and organic matter which decomposes to produce dissolved methane, hence the name *methanic*.

The most important addition to this simple scheme was the addition of the so-called *suboxic* zone at the oxic-anoxic interface, which is defined as the region where concentrations of oxygen and sulfide are both extremely low and have no perceptible gradients (Murray et al. 1989).

The redox zonations, translated to the open ocean, are based on the sequential thermodynamic availability of electron acceptors to oxidize organic matter during respiration processes. These so-called metabolic zones have names depending on the electron acceptor available and are subdivided into “oxic/► [aerobic respiration](#)” (electron acceptor being O_2), nitrate reduction (NO_2^- , NO_3^-), manganese reduction (MnO_2), iron reduction ($FeOOH$), sulfate reduction (SO_4^{2-}), and methanogenesis (CO_2) (Canfield and Thamdrup 2009).

Redshift

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

The redshift is a quantity, generally noted z , that measures the Doppler effect of a celestial object which is going away from the observer, thus whose light exhibits an apparent shift toward a longer wavelength. The term is especially suited for distant objects in the expanding universe (galaxies, quasars, clusters of galaxies), since it supposes that the change of wavelength is positive (the apparent longer wavelength makes the object redder than it is in its restframe). The term *blue-shift* is sometimes used for the reverse situation of an object which is approaching the observer. The redshift gives a direct information on the recession velocity v of the object. For a velocity which is much lower than the speed of light c , the Galilean approximation $z = v/c$ is valid. For velocity approaching the speed of light, a relativistic formulation must be used. Note that there is also a redshift, i.e., a positive change in wavelength, that could be due to a very strong gravitational field; in that case, one speaks of gravitational redshift.

Reducing Agent

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Madrid, Spain

Definition

A reducing agent is a compound that facilitates the ► [reduction](#) of an oxidized compound by a coupled electron transport in an oxidation-reduction process, known as a redox reaction. The reducing agent loses the electron which is transferred to the oxidized compound. Redox reactions are fundamental in biological systems and are involved in all metabolic processes, especially in energy conservation reactions.

Reduction

Concepción Alonso

Universidad Autonoma de Madrid, Madrid, Spain

Keywords

Electron acceptor · Oxidative · Oxidizing agent

Definition

Reduction can be defined in different terms: as a gain of electrons or hydrogen or the loss of oxygen by an atom or a molecule

Overview

Reduction in Terms of Electron Transfer

Reduction is the gain of electrons.

For example, in the reaction between iron and copper sulfate solution,

Copper sulfate and iron sulfate are both ionic compounds. If rewritten as an ionic equation, it turns out that sulfate ions are spectator ions, and the equation can be written as:

It can be seen that copper is *reduced* from copper (II) ions to metal copper (Cu^0) by gaining two electrons

Reduction in Terms of Hydrogen Transfer

Reduction is the gain of hydrogen.

- Hydrogen atoms are transferred from hydrazine (N_2H_4) to oxygen in the following reaction:

Oxygen gains hydrogen and is *reduced* to water.

Reduction in Terms of Oxygen Transfer

Reduction is the loss of oxygen.

- In the following reaction,

Water is *reduced* to hydrogen by the loss of an oxygen atom.

In general terms, reduction implies a decrease in an atom's oxidation state. However, it is only correct to speak about the oxidation state of a metal atom when the compound is purely ionic. Molecules, atoms, or ions that have the ability to oxidize other substances are said to be *oxidative* and are known as oxidizing agents, *oxidants*, or oxidizers. In other words, the oxidant removes electrons from another substance and as a consequence is itself reduced. And, because it "accepts" electrons, it is also called an ► [electron acceptor](#). The electronic transfer reactions known as redox reactions are especially important in biology because most of the biochemical reactions imply reduction or oxidation reactions.

Oxidants are usually chemical substances with elements in high oxidation numbers (e.g., H_2O_2 , MnO_4^- , CrO_3 , $\text{Cr}_2\text{O}_7^{2-}$, OsO_4) or highly electro-negative substances that can gain one or two extra electrons by oxidizing a substance (O, F, Cl, Br).

Reductionism

Christophe Malaterre
Institut d'Histoire et Philosophie des Sciences et Techniques (IHPST), Université Paris I-Panthéon Sorbonne, Paris, France

Keywords

Explanatory reduction · Inter-theoretic reduction · Methodological reduction · Ontological reduction

Definition

Reductionism is a philosophical notion that encompasses a set of ontological, methodological, and epistemological claims about how entities, processes, methods, and knowledge relate to one another across levels of organization and/or scientific domains. Typically, the question is whether such elements at higher levels of organization (i.e., biological) can be deduced from elements at lower levels (i.e., chemical).

Overview

Reductionism encompasses several related claims that revolve around three major types of objects a reduction might concern: the "furniture of the world" (ontological claims), the methods and heuristics of science (methodological claims), theories, explanations, and, more generally, knowledge (epistemological claims) (e.g., Ayala 1974; Sarkar 1992; Nagel 1998).

Ontological reductionism is typically a claim about how entities and processes belonging to a given level of organization can be shown to be entities and processes belonging to a lower level

of organization. For instance, biological entities might be claimed to be constituted by molecules and nothing but molecules in interaction. Such a claim generally entails a metaphysical claim of physicalism. Claims about whether properties (e.g., biological, mental) can be reduced to physical properties remain controversial (so-called type-type reductionism) and are met with opposition by ontological emergentism and non-reductive physicalism (e.g., Kim 1999).

Methodological reductionism asserts that systems at a given level of organization are most fruitfully investigated by decomposition and analysis at lower levels of organization. Even though it is generally accepted that such heuristics can yield scientific knowledge, methodological reductionism remains controversial in that it might lead to overlook interesting generalizations within any given level of organization (e.g., Wimsatt 2006).

Epistemic reductionism concerns claims about how knowledge (e.g., theories, explanations) about entities and processes belonging to a given level of organization (or to a specific scientific domain) might be related to knowledge pertaining to a lower level of organization (or to a different scientific domain). In particular, inter-theoretic reduction encompasses claims about how theories are related to one another, for instance, through relations of logical deduction aided with bridge principles or through relations of successive replacement (e.g., Nagel 1961; Schaffner 1967).

Megaregolith · Lunar soil · Regolith

Definition

Regolith is the cover of loose material overlying the bedrock of a ► [planet](#), satellite, or ► [asteroid](#) and includes fragmented and weathered rocks, soil, and sediments.

Overview

A regolith is the cover or mantle of loose material overlying the bedrock of a planet or other solid solar system body. It includes fragmented and weathered rock debris, soil, and sediments. If present, atmospheres, hydrospheres, or biospheres, as in the case of the ► [Earth](#), play a dominant role in regolith formation. More common, however, are planetary bodies without a dense atmosphere. Here, the regolith is formed and modified by impact processes, mass wasting, and ► [space weathering](#), as on the surfaces of ► [Mercury](#), most of the satellites, and the asteroids. The processes involved, however, vary over time (cratering rate and impactor size), with gravity and the heliocentric distance (kinetic energy and space weathering).

The best-studied example of a planetary regolith is the lunar case. During the period of Heavy Bombardment, the lunar ► [crust](#) was deeply fractured and fragmented by large impacts, generating a global layer of impact debris that may reach a

cumulative thickness of several kilometers. On the Moon, this chaotically mixed layer is termed the “megaregolith.” After the Heavy Bombardment, smaller-sized impacts resulted in a finer-grained surface layer that is only a few meters to some 10 m thick. It is continuously turned over and tends to be homogenized. The overall growth rate in thickness decreases over time because the regolith itself protects the underlying material. Only rare larger impact events are able to excavate fresh material, and the superposition of ejecta blankets creates a layered regolith structure. This uppermost pulverized surface layer is normally referred to as “the lunar regolith.” Typically, it has an average grain size of 60–80 μm and constitutes a poorly sorted pebble- or cobble-bearing silty sand. The term “lunar soil” refers to the <1 mm grain size fraction of the lunar regolith.

In analogy to the lunar case, the term regolith as used in astronomy is often used to refer only to the uppermost finer-grained layer of a planetary surface that is not protected by a dense atmosphere.

Replication (Genetics)

Enrique Viguera
Genetics Department, Sciences Faculty,
University of Malaga, Malaga, Spain

Keywords

Cell cycle · DNA polymerase · Fidelity ·
Nucleotides · RNA polymerase · Template

Synonyms

[Nucleic acid duplication](#)

Definition

Replication is the process by which a nucleic acid molecule is duplicated. DNA replication is required before cell division, ensuring that each daughter cell contains a copy of the ► [genome](#). In eukaryotes, chromosomal replication occurs in the cell nucleus, during the S phase of the cell cycle. DNA replication proceeds in a semiconservative manner in which each of the parental strands of the DNA double helix acts as a template for the nascent strand. A DNA polymerase enzyme catalyzes the formation of a phosphodiester bond between a free 3'-hydroxyl radical of a ► [primer](#) DNA chain and an incoming deoxyribonucleotide, so that replication proceeds in the 5–3' direction. RNA replication occurs during the infective cycle of viruses with RNA genome (with some exceptions including retroviruses which retro-transcribe their genomic RNA into DNA).

Overview

DNA replication in vivo requires three steps: (1) initiation of the polymerization of a DNA

chain, (2) elongation, and (3) termination. DNA replication initiates at a specific site, the origin of replication, that controls the replication of a unit of DNA called a replicon. Most bacteria and viral chromosomes contain a unique replication origin, whereas eukaryotes contain multiple replication origins. Replication of chromosomes can proceed in a unidirectional or bidirectional mode, whereas a rolling circle mechanism has been described for the replication of some viral chromosomes. Origins of replication are recognized by initiator proteins that induce the opening of the DNA double helix and recruit other proteins to constitute the replication fork (a Y-shaped region of DNA that results from the separation of the DNA strands at which replication of new strands takes place; Fig. 1). Because of the 5–3' polarity of replication, one strand is synthesized in a continuous manner (leading strand) and the other in a discontinuous manner (lagging strand). The leading strand is primed at the origin, whereas the lagging strand is primed by a primase enzyme which synthesizes an RNA primer that is later elongated by the DNA polymerase (generating the so-called Okazaki fragment). The replication machinery that moves along the DNA during the elongation step is called the replisome. Termination occurs when two oppositely migrating replication forks meet each other. Accidental termination of a replication fork might be lethal unless the replication machinery is reassembled by the action of ► [recombination](#) proteins or the DNA region is replicated by a convergent replicating fork.

RNA ► [virus](#) replication depends on RNA-directed RNA polymerases that catalyze replication of RNA from an RNA template. These polymerases lack an error correction mechanism, which explains partly the high ► [mutation](#) rates of RNA viruses.

DNA can be replicated in vitro by a DNA polymerase, using a DNA template, a primer that pairs with the template and provides a 3'-OH end to be extended, the four deoxyribonucleotides triphosphate (dATP, dTTP, dCTP, and dGTP), and metal ions. The sequence of the DNA template dictates the complementary ► [nucleotides](#) to be inserted into the nascent strand. DNA replication fidelity relies on the high ► [nucleotide](#)

Replication (Genetics), Fig. 1 Electron micrograph of a plasmid DNA restriction fragment from the bacterium *Escherichia coli* containing an internal replication bubble (upper). Plasmid replication intermediates were isolated and digested with a specific restriction enzyme. The DNA samples were extracted with phenol, filtered by passage through Sephadex LH60, and prepared for electron microscopy by cytochrome c spreading in 50% formamide and carbonate buffer on a water hypophase. The spreading film was picked up with Parlodion-coated cooper grids, the DNA was shadowed with platinum/iridium (80:20), and micrographs were recorded using a Phillips EM400 electron microscope. The bar corresponds to 1 μ m. (Authors: Enrique Viguera, Bernardo Schwartzman and Rudy Lurz)

selectivity of the DNA polymerase and the editing of the misinserted nucleotides (thanks to the proofreading activity of the DNA polymerase). DNA polymerases lacking this 3–5' exonuclease activity (as well as RNA-directed RNA polymerases) have reduced fidelity. Amplification of a DNA template may be carried out by ► [polymerase chain reaction](#) using thermostable DNA polymerases or by isothermal amplification using a DNA polymerase endowed with high strand displacement activity (the DNA polymerase of the virus Phi29). DNA replication blockage in a repeated sequence can lead to the generation of deletions or expansions in the DNA ("indel" mutation) by a replication slippage mechanism.

[Oxidative phosphorylation](#); [Respiratory chain](#)

Definition

At cell level, respiration is the process in which biological systems oxidize different substrates, where the oxidizing agent is a substance that is external to the system itself. Historically, the term has been used when the substance which is the external ► [electron acceptor](#) is oxygen (► [aerobic respiration](#)). However, this definition should be

widened to include the cases where the external electron acceptor is a substance other than oxygen (anaerobic respiration).

Overview

Respiration is a common way for living organisms to obtain energy. The process is a source of oxidation for various cellular components, such as NADH, succinate, acyl-CoA, etc., which are produced either by the catabolism of substances taken from the exterior or directly from a component taken from the exterior, such as methanol (this is the case for *Paracoccus denitrificans*, which can grow on methanol) or Fe^{2+} (in the case of *Acidithiobacillus ferrooxidans*). The final electron acceptor in the case of eukaryotic cells and multicellular organisms is oxygen, although, in the absence of oxygen, the final electron acceptors in many bacteria are other components, such as nitrate, nitrite, sulfate, or fumarate (compare a and b in Fig. 1). Bacteria are therefore highly versatile with respect to the use of final electron acceptors, and the actual electron acceptor used is frequently dictated by the specific external conditions. For example, although *Escherichia coli* can respire oxygen, in the absence of oxygen it can respire fumarate and nitrate. This ability allows many bacteria to be extremely diverse and adaptable.

The electron transfer from the initial donor to the final acceptor is performed by means of an electron transport across a series of intermediaries, whose composition is universal. When referred to as a whole, these intermediaries are usually called the respiratory chain or electron transport chain. As shown in Fig. 1, three of these intermediaries are proteins (flavoproteins, iron-sulfur proteins, and cytochromes), while one is lipid in character (quinone). In the case of proteins, it is the prosthetic group which takes part in the redox reactions, although the polypeptide, apart from maintaining the global structure of the systems, also modulates the ► [redox potential](#) of the prosthetic groups. The majority of these components are not free in a solution, but form macromolecular complexes inserted in cell membranes, specifically in the internal mitochondrial

membrane in the case of eukaryotic cells or in the plasma membranes of bacteria. Exceptions to this are the quinones, which freely diffuse in the apolar phase of the lipid bilayer of the membranes and some cytochromes, such as cytochrome *c* in mitochondria. The number and composition of these complexes vary from one organism to another, although there are always two of them present: an initial dehydrogenase/oxidase, which takes electrons from the primary donor, and a final oxidase that transfers them to the final acceptor. The composition of both complexes obviously depends on what the initial donors and final acceptors are. Therefore, the initial complex in mitochondria may be NADH dehydrogenase, succinate dehydrogenase, acyl-CoA dehydrogenase, etc., depending on whether the initial donor is NADH, succinate, or acyl-CoA; and the final complex is a cytochrome *c* oxidase that transfers electrons from the cytochrome *c* to O_2 (Fig. 1b). In contrast, *E. coli* displays higher versatility with respect to the final acceptor, as it may be a cytochrome oxidase, but may also be a nitrate reductase, if the final acceptor is nitrate (Fig. 1a).

Why are electron transport chains located in the membranes and so highly organized? As mentioned above, the main purpose of the process is to use the free energy released by redox reactions, translating them into an energy currency that the cell can use for other endergonic processes that take place there. Since the first half of the twentieth century, it has been known that ATP is produced as a result of respiration, which is why this phenomenon is commonly known as oxidative phosphorylation (phosphorylation of ADP to produce ATP as a consequence of the oxidation processes). However, it was a long time before the mechanisms which facilitate energy coupling between the two processes were clearly established. Today, it is universally accepted that the first energy coupling does not take place directly between oxidation and phosphorylation, but between oxidation and the expulsion of H^+ from the membrane in which the process takes place. That is to say, the first energy coupling takes place between a chemical reaction (oxidation-reduction reaction) and a transport process (H^+) across a membrane. In other words, the

Respiration, Fig. 1 Examples of respiratory chains. (a) The diversity of bacterial respirations is shown as a combinatorial of electron donors and acceptors (shown as pairs of acceptor/donor) of diverse reducing potential. The electron flow (arrows) is coupled with the generation and maintenance of a proton-motive force through a membrane where the electron transport chain components are located. (b) The oxygen respiration in mitochondria is a subset of

electron transport machineries of bacterial origin. Multi-subunit transporters are represented as boxes, whereas monomeric cytochrome *c* is represented by a circle; membrane-soluble quinones (*MQ* menaquinone, *UQ* ubiquinone) are shown in gray; *cyt c* cytochrome, *FeS* iron-sulfur cluster, *NDH* NADH dehydrogenase, *SDH* succinate dehydrogenase

chemical reaction “energizes” the membrane, causing a proton electrochemical potential difference between the two sides. The H^+ reentry is coupled to the ATP synthesis, a process in which a protein complex, which has been given the generic name of proton-translocating **ATPase** or ATP synthase, is involved. This is why membranes are so important throughout the process.

As has been mentioned above, during respiration, there is a coupling between a chemical reaction (redox reactions) and a transport process (of H^+). In order for the coupling to take place, the respiratory chain complexes have to be organized, which means that the different groups which take part in the reactions are specifically

positioned relative to each other and with respect to the inner and outer part of the membrane (anisotropic distribution). Some of the complexes couple the processes using pumps. Essentially, redox reactions cause conformational changes in the proteins of the complex and induce pK variations in certain lateral amino acid chains, which finally lead to a proton transport from the interior of the system toward the exterior. In other cases, coupling occurs through loops, as the complexes have alternating groups which take part in redox reactions which involve and do not involve protons, respectively. These groups release the first protons, taken from the interior during the reduction process, to the

exterior on being oxidized, if the following acceptor does not accept protons.

Basic Methodology

- Methods for the detection of redox centers. Different techniques have been required, depending on the nature of these centers. For this reason, cytochromes have usually been detected using spectroscopy absorption, since these molecules have very different absorption spectrums in the visible region depending on their state of oxidation. Electron spin resonance spectra (ESR) have frequently been used in the case of iron-sulfur proteins, while a combination of both the above techniques has been used for quinones. Redox potentiometry has also been frequently used in order to measure the redox potentials of the different intermediaries in the respiratory chain.
- One of the crucial points in the coupling of processes is determining the stoichiometry of the coupling. In the case of the respiratory chain, the stoichiometry is the relation between the number of protons expelled across the membrane and the number of electrons transported in the respiratory chain. A classic experiment for measuring this relation in the case of mitochondria is the oxygen pulse. This consists of adding a controlled amount of oxygen and a reducing substrate (e.g., succinate) to a suspension of mitochondria incubated in anaerobic conditions, and an ADP-free medium, and using H^+ microelectrodes to detect variations in the concentration. Variations of this experiment can be carried out using submitochondrial particles (particles obtained with a suspension of mitochondria exposed to ultrasound, in which the membrane is inverted relative to the membrane of the intact mitochondria) or with liposomes in which different complexes of the respiratory chains have been inserted after having been separated by treatment with detergents.
- X-ray diffraction of crystallized complexes. This has been used to determine the three-dimensional structure with atomic resolution

of many respiratory chain complexes. Up until now, the majority of them were from bacteria, since mitochondrial complexes are made up of a larger number of subunits which are more difficult to crystallize. This experimental determination has played a key role in explaining the precise mechanisms and sequence of events in electron transport in the respiratory chain, as well as determining the loop and pump mechanisms required to couple the transport to proton expulsion.

Key Research Findings

The chemiosmotic hypothesis of coupling between electron transport and ATP generation mechanisms was proposed by Peter Mitchell in 1961. He suggested that a proton electrochemical potential gradient is generated between both sides of the internal mitochondrial membrane and is an intermediary in both processes (respiration and ATP generation). Almost simultaneously, similar experiments suggested that there are identical mechanisms for ATP generation in bacteria and for photosynthetic phosphorylation (ATP generation in chloroplasts and photosynthetic bacteria, as a result of light absorption).

The three-dimensional structures of many respiratory chain complexes have been obtained since the last decade of the twentieth century. From these, many of the mechanisms for the electron transport through the respiratory chain as well as the mechanisms for the translocation of protons across the membranes coupled with this transport have been elucidated.

Phylogenetic analyses indicate that the last universal common ancestor have been a cellular entity with the ability to synthesize ATP using the electrochemical potential gradient generated by electron transport chains.

Applications

Over time, our understanding of the respiration of many bacteria has increased, in particular with regard to extremophiles, such as *Acidithiobacillus*

ferrooxidans, which lives in very acid environments and respire oxygen, even though the ► [electron donor](#) in its respiratory chain is Fe^{2+} from the surroundings (one could say it “eats” Fe^{2+}), as well as for many other bacteria which have different electron donors and acceptors. This increased understanding has enabled us to envisage systems where the respiratory chain organization is much simpler and helped us to come closer to the evolutionary origin of this mechanism, thereby allowing us to make conjectures about possible organizations in scenarios different to those on earth.

Furthermore, the elucidation of respiratory systems has led to a wider understanding of many physiological mechanisms, such as heat generation in mammals, or the cause of oxidative stress and possible solutions. An understanding of these mechanisms will, in a not too distant future, enable us to modify them to obtain specific results.

Rhea

Therese Encrenaz
LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

Rhea, discovered by Giovanni Domenico ► [Cassini](#) in 1672, is the largest of the mid-sized icy satellites of Saturn. Its distance to ► [Saturn](#) is 527,000 km (or 8.7 Saturnian radii). Its diameter is 1528 km and its density is 1.24 g/cm³, typical of a water-ice body. Rhea was first observed by Voyager 1 in 1980 and then more extensively explored since 2005 by the Cassini orbiter. The surface of Rhea is heavily cratered with little differentiation, with the exception of Izanagi crater, which is 250 km in diameter. Rhea has no orbital resonance with any other satellite, which accounts for the lack of tidal heating and hence of geological activity.

Definition

Rheology (from the Greek words *ῥεῖ* (*rhei*), “to flow,” and *λόγος* (*logos*), “teaching”) is the science of the flow and the deformation of matter in response to an applied stress.

Overview

Planetary interiors and surfaces are composed of solid and liquid silicate ► [rocks](#), metals, and ices, which deform and flow under an applied non-hydrostatic stress σ (in [Pa]). If the applied stress is small, the material behaves elastically. This means that the material returns to its initial state after the stress is removed. Real planetary materials exhibit a plastic, nonreversible rheological component, in addition to their elastic behavior. In this case, the material does not fully return to its initial state after the stress is removed.

Plastic rheologies are characterized by a maximum stress, called yielding stress, above which perfect elasticity is lost. For nonelastic rheologies the relative deformation, called strain ϵ (dimensionless) and caused by a constant stress σ_0 , is time dependent.

Any time-dependent stress-strain relation is called creep, and planetary rheology studies the flow laws of the creep of planetary materials.

There are three regimes of creep behavior: the transient (I), the stationary or steady-state (II), and the tertiary (III) creep regime. Figure 1 shows the time dependence of creep for the three different regimes when a constant stress σ_0 is applied.

The elastic component leads to an instantaneous deformation resulting in a constant strain ε_0 . For small times, creep is in the transient regime (I), where strain increases with a decreasing rate. There are many ways of describing transient creep mathematically, but all fail at certain timescales (see Jaeger et al. 2007 for in detail discussion). One possible mathematical description is to use:

$$\varepsilon_1(t) = a_1 \cdot t^{b_1} \text{ with } 1 > b_1 > 0 \quad (1)$$

where $\varepsilon_1(t)$ is the strain in regime (I) as a function of time t . This approach, however, fails for $t \rightarrow 0$ as the strain rate approaches infinity. It also does not smoothly transfer into the steady-state creep regime (II) at intermediate times, where the strain ε_2 increases linearly with time:

$$\varepsilon_2(t) = a_2 \cdot t \quad (2)$$

For long timescales, the tertiary regime (III) is reached where the strain $\varepsilon_3(t)$ increases with an increasing rate, until material failure occurs.

A more realistic description of planetary creep $\varepsilon(t)$ would involve the instantaneous (elastic) material response combined with the three time-dependent (plastic) creep regimes described above:

$$\varepsilon(t) = \varepsilon_0 + \varepsilon_1(t) + \varepsilon_2(t) + \varepsilon_3(t) \quad (3)$$

Several rheological models partly satisfy the creep behavior shown in Fig. 1.

We discuss briefly some of them: Fig. 2 shows a summary of rheological models, which are often applied to the flow behavior of geological materials present in the interiors and lithospheres of planetary bodies.

In response to an applied stress σ_0 , elastic material behavior results in an instantaneous strain ε_0 (Fig. 2a), which can be described in terms of a spring with elastic constant k :

Rheology, Planetary Interior, Fig. 1 Schematic view of distinct creep regimes (strain evolution with time) in the event of constant stress applied: instantaneous (elastic) response, (I) transient, (II) stationary, and (III) tertiary creep regime. See text for further explanation

$$(\sigma = k \cdot \varepsilon) \rightarrow \left(\varepsilon_0 = \frac{\sigma_0}{k} \right) \quad (4)$$

In this model, any material relieved from the applied stress reversibly returns to its initial state.

To model irreversible, plastic processes, such as the stationary creep domain (II), a viscous rheology is needed, which is described by a dash-pot with the ► viscosity η (Fig. 2b). Here, strain increases linearly with time.

$$\varepsilon = \frac{\sigma_0}{\eta} \cdot t \quad (5)$$

The Earth's mantle and also the interiors of many other planetary bodies are often modeled in terms of a Maxwell or a Burgers rheology. The Maxwell rheology is described in Fig. 2c. It is represented by a serial combination of elastic and viscous elements. It therefore describes the instantaneous and the stationary creep to a certain degree. For stresses varying on short timescales, the Maxwell body responds like an elastic spring while on long timescales the Maxwell body flows. The transition between these two regimes occurs at the Maxwell time η/k . To also include transient creep (I), it is necessary to combine a Maxwell rheological element in series with a so-called Kelvin element (elastic and viscous elements in parallel). We then obtain the model of the rheology of a Burgers body, shown in Fig. 2d. The Burgers rheology is best suited to model the rheology of

Rheology, Planetary Interior, Fig. 2 Four model representations to illustrate the rheology (strain evolution with time) of rock: (a) an elastic spring can be used to illustrate the elastic response to stress, (b) a dashpot represents plastic deformation in regime (II), (c) an elastic spring in

series with a dashpot represents a Maxwell viscoelastic rheology, and (d) an elastic spring in parallel with a dashpot and in series with an elastic spring and a dashpot, finally, represents the Burgers elastic, transient (I), and viscous response (II)

planetary mantles at a broad range of deformational timescales, as described in the stress-strain relation of rocks shown in Fig. 1. None of these models consider tertiary creep (III).

Basic Methodology

Here, we focus on the rheology of ► mantle material, necessary to model convection and heat transfer in planetary interiors. Mantle material is modeled on geological timescales by using the steady-state creep regime only.

The steady-state parameter a_2 in Eq. 2 depends, among other factors, on stress σ and temperature T . The stress dependence can be described by a general power-law creep with dimensionless exponent n .

$$\varepsilon_2(t) = a_2(\sigma, T) \cdot t = a_2(T) \left(\frac{\sigma}{\sigma_0} \right)^n \cdot t \quad (6)$$

Here $a_2(\sigma, T)$ is a characteristic strain rate (in $[s^{-1}]$). Creep is a thermally activated process, initiated by the diffusion or dislocation of impurities. Therefore, an Arrhenius-type law can describe the temperature-dependent part of the characteristic strain rate $a_2(T)$:

$$a_2(T) = a_2(T \rightarrow \infty) \cdot \exp\left(-\frac{G^*}{RT}\right) \quad (7)$$

$G^* = H^* - TS^*$ is the molar activation Gibbs energy change of the process (in $[J/mol]$), H^* is the molar enthalpy change, S^* is the molar entropy change, $a_2(T \rightarrow \infty)$ is the theoretical strain rate at infinite temperature and R is the universal gas constant. For a negligible molar entropy contribution, we can focus on the enthalpy change (Karato 2008). This leads to a strain rate stress relation for general power-law creep (Karato and Wu 1993):

$$\dot{\varepsilon}(t) = A \cdot \left(\frac{\sigma}{\mu} \right)^n \cdot \left(\frac{b}{d} \right)^m \cdot \exp\left(-\frac{H^*}{RT}\right) \quad (8)$$

Here A is a constant factor (in $[s^{-1}]$), μ is the shear modulus (in $[Pa]$), b is the length of the Burgers vector (in $[m]$), d is the grain size (in $[m]$), and n, m are dimensionless power-law exponents.

For mantle rheologies, two cases are important:

1. For diffusion-controlled processes linear (Newtonian) creep is important. Here $n = 1$ and $m = 2$ (Karato and Wu 1993). Therefore, the strain rate varies strongly with the grain size of the rock and linearly with differential

stresses. Linear creep is expected to dominate the Earth's lower mantle.

2. In the Earth's upper mantle, dislocation creep is expected to dominate the rheology. Non-linear (non-Newtonian) creep is then assumed to control the flow of rock. In this case, $n \approx 3$ and $m = 0$ (Karato and Wu 1993). Therefore, the flow is insensitive to grain size but depends strongly on the applied stress σ .

Key Research Findings

- The habitability of planets depends on their thermal state, which on the other hand is strongly affected by the thermal history of the planet's interior. The thermal transport within planetary interiors is controlled by the viscosity of mantle material, which depends on the material rheology. Typical viscosities of Earth mantle material range from 10^{17} to 10^{23} Pas (Ranalli 1995).
- ► [Plate tectonics](#) and ► [magnetic fields](#) (around active stars) might contribute to make a planet habitable – and they both depend on the rheology of a planet's mantle: one necessary criterion to obtain plate tectonics is that convective stresses have to overcome lithospheric plate yield stresses. Regenauer-Lieb et al. (2001) have shown that water can promote the initiation of plate tectonics.
- Magnetic field generation depends on the transported heat flux out of the core, which depends on the viscosities in the lower mantle, whereas the rheological creep law determines the viscosities.

Applications

The applications include mantle convection, creep mechanism, geomorphology, tectonics, yielding, plate tectonics, ices (► [Europa](#)), and glaciers (Earth).

Future Directions

Due to the large uncertainties in the exact rheology of planetary interiors, upper limit viscosities

obtained from these flow laws vary for Earth by a factor of 10^6 (Ranalli 1995). For ► [super-Earths](#) viscosity uncertainties are much larger and hence our understanding of ► [super-Earth](#) interiors is limited (Karato 2011; Stamenković et al. 2011, 2012). High-pressure experiments are needed to completely understand the thermal and compositional state of the interior of the Earth, other terrestrial planets, and ► [super-Earths](#).

Definition

In biochemistry, a ribonucleoside is an organic molecule derived from the condensation of a nitrogenous base and the C¹ atom of ribose via a glycoside linkage. Examples of pyrimidine ribonucleosides include uridine and cytidine. Thymine ribonucleoside is sometimes called 5-methyluridine, while thymidine represents the deoxynucleoside of thymine. Pyrimidine ribosides are linked via their N¹ nitrogen atoms. The purine ribosides include adenosine and guanosine, linked via their N⁹ ring atoms. The glycoside linkage may be α - or β -, depending on which face of the ribose ring the nitrogen heterocycle is bonded on. Biological ribosides are β -linked. Nucleosides are phosphorylated to give nucleotides.

Definition

A nucleotide is a phosphorylated nucleoside. ► [Ribonucleosides](#) may be phosphorylated via the oxygen atoms found at C², C³, or C⁵ of the ribose ring. Ribonucleotides have one, two, or three phosphate groups attached to the ribose sugar. In some ribonucleosides, a phosphorus group is bound to two oxygen atoms of the ribose ring, yielding a cyclic nucleotide. Some important examples of these include cyclic 3', 5' adenosine monophosphate (cAMP), an important cellular signaling molecule, and the 2', 3' cyclic nucleotides which may be formed during the nonenzymatic hydrolysis of polyribonucleotides. Ribonucleotides are incorporated into nucleic acids as their triphosphates, with the liberation of pyrophosphate during polymerization. An extremely important energy-carrying ribonucleotide is adenosine triphosphate (► [ATP](#)).

Definition

Ribose is a five-carbon ► [monosaccharide](#) with three chiral centers (aldopentose) found in ribonucleic acid (RNA) and several coenzymes (ATP, B₁₂, NAD(P)H, etc.) with the formula (C₅H₁₀O₅). Ribose has all the hydroxyl groups on the same side in the Fischer projection. Ribose can exist in two enantiomeric forms, D and L. Biological nucleic acids use the D version. Ribose is the precursor to deoxyribose in biology. In water, ribose exists in equilibrium as furanose, open-chain, and pyranose forms (from left to right in Fig. 1). The pyranose form is predominant (76%). D-Ribose must be phosphorylated to d-ribose 5-phosphate before it can be used by the cell's enzymes. Ribokinase catalyzes this reaction. Once phosphorylated, D-ribose 5-phosphate is used for the biosynthesis of the ► [amino acids](#) tryptophan and histidine and in the pentose phosphate pathway. D-Ribose 5-phosphate is further converted to phosphoribosyl pyrophosphate for the biosynthesis of nucleotides.

Ribosomes are essential for accurate ► [translation](#) of the mRNA-encoded genetic message; they biosynthesize ► [proteins](#) by catalyzing the peptide bond formation between tRNA-bound ► [amino acids](#).

Overview

Ribosomes are composed of about 65% RNA and 35% proteins distributed into a small and a large subunit. In contrast to the ribosomal proteins (r-proteins), the ribosomal RNA (rRNA) has been highly conserved during evolution and contains numerous posttranscriptional modifications and peculiar structural features like pseudo-knots and other RNA-RNA tertiary interactions. Ribosomes are present in all organisms from the three

domains of life (*Bacteria*, *Archaea*, and *Eukarya*) and in two eukaryotic organelles originated by ancient ► [endosymbiosis](#) of bacteria (mitochondrion and chloroplast).

The prokaryotic ribosomal subunits have a sedimentation coefficient of 30 S (S stands for Svedberg, the unit of sedimentation coefficient which is proportional to the mass of the particle) and 50 S, respectively, and join to yield a 70 S ribosome with a mass M_r of around 2.7×10^6 and a diameter of 200 Å. In eukaryotes, the complete 80 S ribosome, formed by 40 S and 60 S subunits, has a M_r of 4.2×10^6 and diameter of 300 Å. The crystal structure of the prokaryotic ribosome has shown that the particle inside is mostly made of rRNA: one 16 S RNA molecule in the small subunit and two, 5 S and 23 S RNA molecules, in the large subunit. The r-proteins, about 20 and 30 in the 30 S and 50 S subunits, respectively, are mainly in the surface with extensions that interpenetrate the rRNA to strengthen the particle structure (Moore and Steitz 2005).

During translation, the ribosome binds one mRNA and two tRNA molecules, which can be positioned at three well-defined sites, A, P, and E, at different steps of the process (Burkhardt et al. 1998). Both subunits have different functions (Ogle and Ramakrishnan 2005; Korostelev and Noller 2007). The small subunit participates in the decoding process by controlling the accuracy of the interaction of the mRNA ► [codons](#) with the tRNA anticodons. The large subunit stabilizes the tRNA binding at the A, P, and E sites, displays the peptidyl transferase activity (which catalyzes the formation of the peptide bonds that link together the ► [amino acids](#) in proteins), and contains a GTPase-associated domain involved in the interaction of essential GTP-hydrolyzing factors. Most ribosomal functions are directly associated to the rRNA, while r-proteins optimize the activity by providing the appropriate conformation (Moore and Steitz 2005). During translation, the large subunit rotates relative to the small subunit in a ratchet-like manner, which drives the displacement of the ribosome along the mRNA (Frank and Spahn 2006).

A comparable core structure is present in all ribosomes despite which taxonomic group they

belong to. Ribosomes from eukaryotic organelles are of the prokaryotic 70 S type (Harris et al. 1994). In the cytoplasm, larger 80 S eukaryotic ribosome extra RNA loops are found as continuous insertions in the conserved rRNA core where additional proteins bind (Spahn et al. 2001). The role of these additional components is unknown but might perform some control function.

The ribosome is the target of a number of ► [antibiotics](#), which bind to the rRNA and block ribosomal functions (Yonath 2005). Consequently, translation and cell growth stop. The antibiotic specificity for either prokaryotic 70 S or eukaryotic 80 S ribosomes determines its clinical usefulness (Vazquez 1979).

Synonyms

[RNA enzyme](#)

Definition

An abbreviation of “ribonucleic acid ► [enzyme](#).” Broadly defined as an ► [RNA](#) molecule that catalyzes any specific chemical reaction even though it may not always satisfy the strict definition of “enzyme,” specifically with respect to multiple turnover and self-modification.

History

The concept of catalytically active RNA was first postulated in the late 1960s as part of an elegant scenario to describe the origin of life (Woese 1967; Crick 1968; Orgel 1968). Subsequently, the unexpected discovery in the early 1980s that ribozymes were, in fact, active and essential components of contemporary living organisms was a paradigm-shifting breakthrough. Tom Cech, studying intron splicing (an intron is a region of RNA that interrupts the protein-coding region of some messenger RNAs and which must be removed in a process called RNA splicing before the mRNA can be correctly translated into a protein) (Kruger et al. 1982), and Sidney Altman, investigating ribonuclease P (an RNA/protein enzyme that cleaves the leader sequence from precursor transfer RNAs to generate mature tRNAs) (Guerrier-Takada et al. 1983), demonstrated that the catalysts of their respective chemical transformations were, remarkably, the RNA molecules themselves. For their discoveries, Cech and Altman shared the 1989 Nobel Prize in Chemistry.

Overview

Prior to the discovery of ribozymes, it was assumed that proteins were the sole catalysts in biology. Since their initial discovery, roughly a dozen families of natural ribozymes, distributed across all three domains of life, have been isolated. They primarily catalyze various phosphoester transfer reactions, such as RNA splicing and other site-specific cleavage/ligation of the RNA backbone. Their closely related catalytic repertoires are achieved through a variety of unique structural scaffolds. These are utilized in a variety of fundamental cellular processes ranging from regulation

of gene expression to genome replication, but at the chemical level, specializing in reactions that alter the connectivity of the ribose-phosphate backbone of RNA. A notable exception to this rule is the ► [ribosome](#) (the cellular machine responsible for making proteins in all known life), which is composed of both RNA and protein. It was shown in 1992 that the chemical step of peptide bond formation could be reconstituted in ribosomes from which nearly all of the protein had been removed, a strong indication that the RNA was the catalytic component (Noller et al. [1992](#)). This hypothesis was confirmed 8 years later by the X-ray crystal structures of the ribosome showing that the catalytic center of the ribosome is constructed of RNA, with no protein within a radius of 18 Å, thus making the ribosome itself the supreme example of ribozyme catalysis (Nissen et al. [2000](#)).

In vitro evolution and selection has greatly expanded both the number of known ribozymes and the diversity of their catalytic repertoire by enabling the isolation of new ribozymes that have never before been observed in nature (Joyce [2004](#)). The number of in vitro selected ribozymes has now far surpassed that of the naturally occurring ones and includes a wide range of diverse functionalities. The ► [RNA world](#) (Gilbert [1986](#)) hypothesis of the origin of life posits that all contemporary life can trace a direct line of descent to ribozyme-based organisms that flourished and then faded about 4 billion years ago. In vitro selection has been the primary investigative tool used to test the feasibility of this hypothesis, and much of what is known about ribozymes has been learned in this pursuit (Ellington et al. [2009](#)).

Like RNA, DNA is also able to fold into complex three-dimensional structures and catalyze chemical reactions (Joyce [2004](#)). These catalysts are often referred to as deoxyribozymes or DNAzymes. They have not been observed in nature but were discovered using in vitro selection.

RRKM

Definition

Rice-Ramsperger-Kassel-Marcus (or simply RRKM) is a chemical kinetics theory allowing the estimation of unimolecular reaction rates from a few parameters of the potential energy surface. The RRKM theory is an improved form of the Rice-Ramsperger-Kassel (RRK) theory in which the rate an excited reactant molecule breaks down is treated as a function of the energy it contains. The RRKM theory was developed from the RRK theory by taking Eyring's transition state theory, and the way the various normal-mode vibrations and rotations contribute to reaction, into account. The RRKM theory assumes that the rate is proportional to the number of ways of distributing the energy among the internal degrees of freedom of the reactant, in such a manner that the critical energy is localized in one particular degree of freedom. It can be a powerful tool for studying gas-phase molecular reactions, such as those that occur in planetary atmospheres or in the interstellar medium.

Right Ascension

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The right ascension is one of the two coordinates of the equatorial system of reference, used by astronomers to locate a celestial object on the sky. It is the coordinate measuring the angular distance along the ► [celestial equator](#) between that object and the ► [“Vernal point”](#), which is in first approximation a fixed point with respect to the stars. The Vernal point is the location on the sky where the Sun crosses the equatorial plane at the March equinox. Right ascension is measured in units of hours, minutes, and seconds, positively toward the east. Because of the ► [precession](#) of

the equinoxes, the Vernal point moves slowly with time, so that the coordinates (right ascension and ► [declination](#)) must be associated with an indication of the date (the equinox) at which they are valid.

Definition

Río Tinto is a 100-km-long acidic fluvial system (Fig. 1) emplaced in the IPB (Leistel et al. 1998) considered as a chemical environmental analog of Mars (Fernández-Remolar et al. 2005). Since the paleolithic (Mayoral et al. 2021), the Rio Tinto basin has been populated by different cultures and civilizations (chalcolithic, bronze, and iron), which have mined the rich metallic ore bodies for copper, silver, and gold for millennia. The fluvial system is integrated into a wider acidic

Rio Tinto, Fig. 1 Images showing the Río Tinto acidic system in the headwaters around Peña de Hierro (a), and in the Berrocal area (b) showing red deposits enriched in ferric oxyhydroxides and oxysulfates that are sourced in the subsurface bio-oxidation of the sulfide ore bodies by

iron and sulfur oxidizers. The Río Tinto waters experience a high saturation in Fe^{3+} and SO_4^{2-} -bearing ions by means of evaporation conferring a high preservation potential for biological information

domain that included the fluvial basin of the Odiel River, where early Quaternary deposits of acidic origin are also found. Río Tinto Headwaters are composed of two main acidic streams sourced in Peña de Hierro and Cerro Colorado areas, respectively. Its peculiar geochemistry is maintained by different low-pH springs sourced on a pyrite ore body aquifer (Gómez-Ortiz et al. 2014) that is bio-oxidized by iron and sulfur bacteria. The Río Tinto springs are connected to the aquifer by a diverse set of normal faults which is recharged with meteoric waters replenishing the oxygen to the underground chemolithotrophs (Fernández-Remolar et al. 2008b). In this frame, the acidic springs are sourced in the acidic subsurface waters outflowing through the same group of faults. The Río Tinto microbial life displays a high microbial diversity despite the extreme conditions based on a low pH and high metal concentration (Amils and Fernandez Remolar 2020). The outstanding mineralogy of the fluvial Río-Tinto system is analogous to the mineral association found in some Mars regions like Meridiani (Fernández-Remolar et al. 2005; Squyres and Knoll 2005). Consequently, Río Tinto is considered as a valuable terrestrial analog of Mars for inferring geochemical conditions that were involved in the formation

of iron-rich minerals that formed under the same hyperacidic solutions on Mars billions of years ago (Ehlmann and Edwards 2014).

Overview

The acidic environment of Río Tinto in Southern Spain (Fig. 1) is the result of the biooxidation of IPB sulfide ore bodies by chemolithotrophs over the last 25 million years (Essalhi et al. 2011; Fernandez-Remolar et al. accepted). The bio-oxidation results from a two-stage process (Sand et al. 2001) starting with the pyrite-rich ore body oxidation to SO_4^{2-} and Fe^{2+} followed by oxidation of Fe^{2+} to Fe^{3+} . The oxidation of the sulfide ore body is a complex process initiated by the decomposition of pyrite with ferric iron serving as the oxidizing agent, which produces great quantities of Fe^{2+} in solution. After that, Fe^{2+} is oxidized to Fe^{3+} by iron oxidizers using O_2 as the electron acceptor, which is newly available as oxidizing agent for pyrite through chemolithotrophic metabolism. Under acidic conditions, ferric cation is very soluble and functions as a buffer (see chemical formula 2 above) that maintains the pH between 1.5 and 3.5 (Fernández-

Remolar et al. 2003; Gómez et al. 2004). In the multistage oxidation process, the low-pH underground waters enriched in iron and sulfate are exposed to evaporation mainly during the hot season (late spring to early fall), experiencing a subsequent overconcentration to produce acidic brines. Furthermore, the microbial oxidation of pyrite is an exothermal process that, under certain geological conditions, can result in heat accumulation in the subsurface (Fernández-Remolar et al. 2008a). Consequently, both pH and thermal control have been considered as ecological mechanisms with homeostatic properties that could benefit microbial communities on surface and subsurface habitats (Fernández-Remolar et al. 2008a; Gómez et al. 2004). The surface and subsurface areas of the Río Tinto system are greatly influenced by seasonal changes which control the input of rainwater and oxygen to the system (Fernández-Remolar et al. 2003). During the wet season, weathering of silicates, erosion in headwaters, and sedimentation in the fluvial are favored, whereas the precipitation of sulfate assemblages is the main sedimentary process in the dry season (Fig. 2). Therefore, the sedimentary record on the surface environment alternates between detrital fine-grained deposits, iron oxides, and sulfates. The exploration of the Río Tinto basement through the MARTE and IPBSL projects (Amils et al. 2013; Fernández-Remolar

et al. 2018; Stoker et al. 2008) has shown that it has a diverse microbial community is subjected to a varying pH and redox ranging from acidic and aerobic in shallow areas to quasi-neutral and anaerobic in deeper areas, where methane and carbonates are formed by microbial mediation (Fernández-Remolar et al. 2008b, 2018; Puente-Sánchez et al. 2014). The activity of the fluvial environment has been recorded over the last two million years in different terrace levels that have preserved valuable biological information in the form of mineralized structures of micro and macroorganisms, suggesting that biological structures could be fossilized under the same extreme conditions on Mars billions of years ago (Fernández-Remolar and Knoll 2008). Furthermore, the molecular analysis of the ancient ferruginous rocks that were produced under the extreme conditions of the Río Tinto acidic basin supports that the organic compounds and biomolecules are also preserved. Samples from the gossan deposits (> 25-6 Ma) and the upper terrace (2.1 Ma) have provided a diverse association of different biological molecules and inorganic metabolic traces (Fig. 3) (Fernandez-Remolar et al. accepted). While the preservation mechanisms of biomolecules are not fully understood, they might be associated with a fast decrease in water activity coupled with salt mineralization. It strongly reduces or even can inhibit the microbial activity that is associated

Río Tinto, Fig. 2 The red color in water (a) results from the high concentration in different Fe^{3+} plus ionic complexes (e.g., FeSO_4^+ , FeHSO_4^{2+}) that are stable under a pH of 1–3. The riverbed sediments correspond with amorphous polymers of iron and sulfates, which are the precursor of different ferric oxysulfates and amorphous oxyhydroxides precipitating on the river bottom as successive coating layers. The corrugated pattern covering the riverbed (a) corresponds with coated streamers during

successive seasons. In shallow areas, under the extreme summer conditions (b), the acidic brine can eventually evaporate out to precipitate a dark reddish amorphous deposit which is mainly composed of jarosite. Copiapite can also precipitate (b) by pumping evaporation producing characteristic yellowish efflorescence's. Such materials mature to goethite and hematite over time, fossilizing primary sedimentary structures (c) that are found in the terrace ferruginous deposits

Rio Tinto, Fig. 3 Early Pleistocene Upper Terrace (a) cropping at the Alto de la Mesa location (see Fernández-Remolar and Knoll 2008) preserving different micro and macrostructures of biological origin that have been

fossilized by coating and permineralization. (b) Shows the preservation of bisaccate pollen of *Pinus* sp. in the Upper Terrace that is associated with abundant remains of plants, fungi, and insects

Rio Tinto, Fig. 4 ToF-SIMS analysis of a finely laminated deposit collected from the Early Pleistocene Upper Terrace (Fernández-Remolar et al. 2005) showing the occurrence of diacylglycerides at m/z 551.55 ($C_{35}H_{67}O_4^+$) that outline filamentous structures

perpendicular to the laminations. Same lipidic compounds like diverse fatty acids, diacylglycerides, and sphingolipids have been found in the more ancient deposits of gossan dating back to >6 Ma and up to 25 Ma

with organic degradation. Under these circumstances, the preservation of organic compounds and biomolecules could have likely occurred in the ancient acidic deposits of Mars (Fig. 4).

Ribonucleic acid

Definition

Ribonucleic acid (RNA) is one of two principal types of nucleic acid found in all cellular life. RNA consists of a polymer of ribonucleoside phosphates, each unit of which, in turn, is comprised of a ► **pyrimidine base** or ► **purine base**, a ► **ribose** sugar, and a ► **phosphate**. RNAs encode genetic information (e.g., RNA viruses), serve as intermediates in gene transcription (e.g., mRNA), and also play structural, regulatory, and catalytic (e.g., ► **ribosome**) roles in cellular biology.

Overview

Central Dogma of Molecular Biology

Francis Crick proposed a simple scheme, shown below, that he entitled “The Central Dogma of Molecular Biology” to serve as a unifying axiom for the emerging field of molecular biology: DNA → RNA → Protein, i.e., “DNA makes RNA makes Protein.” Information flow was held to be from left to right only, with DNA encoding genetic information, proteins as gene products serving as the main form of genetic expression, and RNA serving an intermediary role.

Although DNA encodes the information required for protein synthesis, it must first be *transcribed* into messenger RNA (mRNA), and then the three-nucleotide genetic code must be *translated* into an amino acid sequence during protein synthesis. In addition to mRNA, which serves as the physical template for translation, adapter molecules, known as transfer RNA (tRNA), match the ► **nucleotide** triplets of the genetic code in the mRNA to individual amino acids, which are covalently linked to each tRNA molecule. Protein synthesis takes place on the ribosome, an RNA-protein complex, whose structure is mainly comprised of ribosomal RNA (rRNA) molecules. The catalytic center of the ribosome is thought to be comprised entirely of rRNA, which also implies the peptidyl transferase of the ribosome is a ribozyme or a catalytic RNA. Bacteria, Archaea, and Eukarya all possess DNA genomes; however, a large subset of viruses possess single-stranded or double-stranded RNA genomes. RNA has recently been shown to be extensively involved in cellular gene regulation via pathways collectively referred to as RNA interference (RNAi).

Messenger RNA (mRNA)

The genetic information encoded in DNA is not immediately available for translation into protein sequences. Rather, this information must first pass through an RNA intermediary known as messenger RNA. Genes are transcribed by RNA polymerases, enzymes that copy a specific sequence of DNA in a template-dependent fashion, producing a complementary single-stranded RNA. Depending upon

the organism, this primary RNA transcript may undergo additional processing steps (e.g., capping, splicing, 3'-polyadenylation) and nuclear export (in the case of eukaryotes) before it becomes a mature mRNA available for translation into a protein sequence.

Mature mRNA molecules typically possess a 5'-untranslated region (5'-UTR), a ribosome-binding and translational start site, a continuous coding region, one or more stop codons (a translational termination site) and a 3'-untranslated region (3'-UTR), and a polyadenine terminus. Both UTRs may contain regions of RNA that participate in translational (and sometimes transcriptional) regulation. The coding region may be discontinuous in the primary transcript, requiring that the intervening sequences of noncoding RNA (or introns) be excised and the remaining coding regions (exons) be ligated, a process collectively termed pre-mRNA splicing. The coding region in a mature mRNA is almost always continuous and consists of a linear sequence of nucleotide triplets, called *codons*, each of which codes for an individual amino acid. The mRNA thus serves as a mobile template for the assembly of a protein by the ribosome.

Transfer RNA (tRNA)

The one-to-one correspondence between an amino acid (the monomeric building blocks from which proteins are synthesized) and a nucleotide triplet codon is physically manifested in the form of transfer RNA (tRNA). Unlike mRNAs, tRNAs are comparatively small (~75 nt) noncoding RNAs that fold into a regular, well-defined globular three-dimensional structure. tRNAs serve as shuttle molecules, one end of which becomes covalently attached to a specific amino acid (via a reaction catalyzed by tRNA synthetase) and the other end, termed the anticodon, forms standard Watson-Crick hydrogen-bonded base pairs with the corresponding codon within an mRNA when both are bound to the ribosome. tRNAs having covalently bound amino acids are referred to as aminoacylated tRNAs, and these (along with the mRNA template) are the substrates used by the ribosome for enzymatic peptide synthesis.

Ribosomal RNA (rRNA)

The ribosome is an RNA/protein complex that catalyzes peptide bond synthesis reactions in a template-dependent manner to *translate* the genetic code into protein sequences. The substrates consist of aminoacylated tRNAs and an mRNA template. The ribosome itself is comprised of two subunits, conventionally termed the large subunit (which contains the peptidyl transferase reaction center) and the small subunit (which binds the mRNA template). Each of these subunits, in turn, is comprised of RNA and protein components. The RNAs define the core structure and appear to be primarily responsible for catalyzing the chemical step of peptide bond formation, as well as forming the binding sites for mRNA, the tRNAs, and the interface between the ribosomal subunits. The proteins are primarily found on the surface of the ribosome and appear to play more ancillary (but nonetheless essential) roles. The small subunit of the ribosome is comprised of several proteins and one RNA molecule (16S rRNA in prokaryotic systems and 18S rRNA in eukaryotic systems, where S indicates ► [Svedberg units](#)). The large subunit of the ribosome is comprised of several proteins and more than one RNA molecule (23S rRNA and 5S rRNA in prokaryotic systems and 28S, 5.8S, and 5S rRNA in eukaryotic systems). The 23S rRNA in prokaryotes and the analogous 28S rRNA in eukaryotes are believed to possess all of the components required to catalyze the chemical step of the peptide transfer reaction; hence, these RNAs are examples of enzymatic RNAs or ► [ribozymes](#).

Catalytic and Enzymatic RNAs (Ribozymes)

Until the early 1980s, it was presumed that all enzymes were proteins. It was then discovered that the self-splicing catalytic activity in group I introns in certain protozoans (e.g., *Tetrahymena*) and the enzymatic processing of precursor tRNA transcripts by the RNA/protein complex RNase P in bacteria were in fact catalyzed by RNA. Subsequently, several other RNA enzymes, or ribozymes, have been discovered. Inarguably, the most important of these, described in the previous paragraph, is the peptidyl transferase activity of the ribosome; hence, the ribosome is the most fundamental and important ribozyme. With

the exception of the ribosome, all naturally occurring ribozymes catalyze either phosphodiester isomerization reactions (leading to both RNA backbone cleavage and ligation) or phosphodiester hydrolysis reactions (leading exclusively to RNA backbone cleavage).

Genomic RNA

All eukaryotic, archaeal, and bacterial genomes are comprised of double-stranded DNA. However, many viruses possess either single-stranded or double-stranded RNA genomes. An important subset of these viruses are known as retroviruses and are characterized in having a life cycle in which an RNA strand that invades the host cell is reverse transcribed by an RNA-dependent DNA polymerase into DNA and the complementary DNA becomes integrated within the host's genome (the human immunodeficiency virus (HIV) is one such example). RNA viruses that are not retroviruses include the common cold virus, influenza viruses, severe acute respiratory syndrome (SARS) virus, polio, and many others.

RNA Interference (RNAi)

Within the last decade, we have begun to understand that small (typically ~21-nucleotide) noncoding RNA molecules that are the products of cellular processing reactions are intimately involved in gene regulation via a series of related mechanisms collectively known as RNA interference (RNAi). Briefly, these mechanisms involve intermolecular interactions between the small noncoding RNAs and mRNAs, or in some cases, direct interaction with the nucleosome.

RNA World Hypothesis

The discovery that RNA can be catalytic provides a logical escape from the conundrum implicit in the Central Dogma of Molecular Biology. Specifically, if proteins are required to replicate ► [nucleic acids](#) and nucleic acids are required to encode proteins, which came first? This sort of paradox is typically invoked as an example of “irreducible complexity” by those arguing in favor of the necessity of a supernatural origin of life. However, if a single type of molecule, such as RNA, is capable of both information storage and catalysis, it means, in principle, that RNA has the

capacity to self-replicate. A self-replicating RNA thus avoids the chicken or egg paradox objection of “irreducible complexity” and permits suggestion that some of the earliest self-replicating molecules may have been RNAs. This conjecture, originally articulated by Carl Woese and Francis Crick, has been formulated and given the title of the ► [“RNA World.”](#) Of course, no one knows if life evolved from an RNA world, but it may be possible to give an experimental proof of principle by creating self-replicating RNAs in vitro. In vitro RNA evolution is now a commonly used laboratory technique for devising various aptamers and catalysts. Although ligase ribozymes have been developed that can copy other RNA sequences in a template-dependent manner (a prerequisite to propagation of RNA), a true self-replicase ribozyme remains elusive.

Department of Biochemistry, Molecular Biology and Biophysics & BioTechnology Institute, University of Minnesota, St. Paul, MN, USA

Keywords

RNA world · SELEX · Ribozyme · Artificial protein enzyme

Definition

RNA ligases are enzymes that catalyze formation of a covalent linkage between two oligoribonucleotides via a phosphodiester bond. In the context of the “RNA world” hypothesis, this linkage reaction would have been of great importance to generate longer, more complex RNA molecules from shorter oligonucleotides, which are easier to synthesize from mononucleotides.

Overview

Because no dedicated RNA ligase ribozymes had been found in nature, the SELEX technology was

applied to isolate artificial ribozymes from a combinatorial library of random RNA. The identified ribozymes catalyze the bond formation of a 5'-triphosphorylated RNA to the 3'-hydroxyl group of a second RNA molecule forming the natural 3–5' phosphodiester linkage (Bartel and Szostak 1993):

These ribozymes were the first artificial ribozymes created in the laboratory and are also some of the most efficient RNA enzymes made to date. Subsequently, the RNA ligase ribozymes were optimized through in vitro evolution to catalyze RNA polymerization (Johnston et al. 2001). This activity would have been the most crucial catalytic function in an “RNA world” enabling the replication of the RNA genome.

Artificial deoxyribozymes that catalyze the same RNA ligation reaction as above were also isolated in the laboratory, using a similar in vitro selection approach (Purtha et al. 2005).

No natural protein enzyme is known to catalyze this RNA ligation reaction shown above. Yet, natural protein enzymes can ligate two RNA molecules by the chemically different reaction linking a 5'-monophosphate RNA to a 3'-hydroxyl RNA while using adenosine triphosphate as a cofactor. In contrast, laboratory evolution using the mRNA display technology has generated an artificial protein enzyme from combinatorial libraries of randomized proteins that catalyze the same RNA ligation chemistry as the ribozymes (Seelig and Szostak 2007). This artificial protein enzyme was found to have an unusual novel structure that is unlike extant proteins. This new enzyme can be considered a model primordial catalytic fold as it has not been shaped by billions of years of natural evolution (Chao et al. 2013).

Synonyms

[DNA \(or RNA-\)-dependent RNA polymerase](#); [RNA replicase](#)

Definition

RNA polymerase is an enzyme which catalyzes the addition of a ribonucleoside triphosphate to the 3' – end of a RNA strand using a template. The systematic name of this enzymatic activity is nucleoside triphosphate-RNA nucleotidyltransferase, and the catalyzed reaction can be represented as

DNA-directed RNA polymerases (EC 2.7.7.6) use DNA templates, whereas RNA-directed RNA polymerases (EC 2.7.7.48) use RNA templates. These enzymes can initiate a chain de novo. In eukaryotes different RNA polymerases participate in the transcription of the diverse types of RNA. In prokaryotes, a multimeric RNA polymerase performs the transcription of the different classes of RNA.

History

Sam Weiss, Audrey Stevens, and Jerard Hurwitz discovered independently the DNA-dependent RNA polymerase activity in 1960.

RNA Replicase Ribozyme

Mark A. Ditzler
Ames Research Center, Moffett Field, CA, USA

Definition

An RNA replicase ribozyme is an RNA enzyme (ribozyme) that catalyzes the replication of RNA sequences. RNA replicase ribozymes are a central feature of RNA world theories of the origin of life.

History

The term RNA replicase was introduced to describe protein enzymes that polymerize RNA in an RNA-dependent manner (Haruna et al. [1963](#)). These protein enzymes replicate the genomes of RNA viruses through the template-directed polymerization of mononucleotides. It was not until decades later that ribozymes capable of similar polymerization reactions and RNA replication were identified through directed evolution in vitro (Johnston et al. [2001](#); Lincoln and Joyce [2009](#)).

Overview

The replication of information-containing molecules by a replicase provides a means of establishing heritability. The emergence of such a replicase would therefore satisfy one of the fundamental requirements of life. RNA's dual biological role of both catalyzing chemical reactions and storing genetic information suggests the possibility of a simple evolving system in which RNA acts as both the replicase and the replicated genome. This possibility of supporting an evolving system with a single type of molecule has motivated a number of efforts to identify and characterize RNA replicase ribozymes. While these ribozymes are not observed in extant biology, RNA-catalyzed replicase activity has been characterized in vitro.

Replicase function can be realized through the ligation of short oligomers. RNA replicase ribozymes that link together short RNA oligonucleotides have been used to generate cooperative, self-replicating systems in vitro. The ribozymes in these systems were adapted either from biological RNA sequences (Vaiday et al. [2012](#)) or from ribozymes evolved from random sequences in vitro (Lincoln and Joyce [2009](#)). These systems demonstrate that RNA-only systems can support self-replication. They do, however, depend on an external supply of oligonucleotide substrates to sustain self-replication, which places limits on the extent to which the behavior of these systems can be applied to understanding the origin of life.

These limits are partially addressed by attempts to identify RNA replicase ribozymes that depend on simpler substrates.

RNA replicase ribozymes that use simple nucleotide monomers as substrates may have greater relevance to the origin of life than replicases that depend on the ligation of oligonucleotides. Ribozyme-catalyzed replication of RNA genomes from monomers requires the existence of ribozymes with template-directed RNA polymerase activity. The existence of such ribozymes has been demonstrated through the iterative application of directed evolution in vitro (Johnston et al. 2001). Initially, ribozymes evolved to catalyze the ligation of two RNA oligonucleotides also exhibited limited polymerase activity (Eklund and Bartel 1996). This activity was enhanced through additional applications of directed evolution to generate more efficient polymerase ribozymes (Johnston et al. 2001; Zaher and Unrau 2007). One polymerase ribozyme is capable of polymerizing >200 nucleotides in a template-directed manner (Attwater et al. 2013). This polymerase ribozyme is only 202 nucleotides long, which suggests that RNA self-replication may be possible. This specific ribozyme has sequence-dependent requirements that prevent it from using its own full sequence as a template for polymerization and therefore does not possess self-replicase activity. An RNA self-replicase that utilizes nucleotide monomers to generate additional copies of itself has not yet been identified.

[RNA life](#)

Definition

The RNA world is a hypothesized early stage in the evolution of life that may have preceded the ► [last universal common ancestor](#) (LUCA) of all modern organisms. In this scenario, ribonucleic acid (► [RNA](#)) was the sole information-rich biopolymer, performing both the catalytic and genetic roles played by proteins and deoxyribonucleic acid (DNA), respectively, in the modern cell. The proposed vestiges of the RNA world are found throughout modern biology, most notably in the central functional roles of RNA found in protein translation.

Overview

Darwin's prediction that all modern life has descended from a single, primitive common ancestor has been thoroughly confirmed by modern biology (Grant and Carpenter 2003). Indeed, comparative genomics has begun to shed light on the genome content of the ► [last universal common ancestor](#) (LUCA), revealing a biochemically sophisticated cellular organism with an extensive metabolism and a fully modern form of protein translation (Koonin 2003; Becerra et al. 2007). To some extent, we can infer that the LUCA itself evolved from more primitive organisms, as paralogous genes present in the LUCA must have descended from a much smaller complement of ancestral genes, but determining how this organism functioned runs into a central dilemma (Wolf and Koonin 2007).

Biology fundamentally uses two classes of informational biopolymer: nucleic acids and proteins. Genetic information is stored and transmitted through inheritance in ► [nucleic acid](#) polymers, primarily in the form of DNA. The ► [phenotype](#) of the cell and by extension the whole organism are directed by proteins, which can fold into complex three-dimensional structures, catalyze diverse chemical reactions, and perform sophisticated mechanical transformations. The central dogma of molecular biology holds that genetic information flows between nucleic acids and from nucleic acids to proteins

but not between proteins or from protein into nucleic acid. This doctrine poses a paradox: proteins are the biopolymer of phenotype, performing the catalytic tasks needed to run a cell, while nucleic acids are the biopolymers of ► [genotype](#), information carriers par excellence. How could either have evolved without the other?

The RNA world offers a solution by predicting that ancestors of modern cells existed in which the primary, if not sole, information-rich biopolymer was RNA. RNA would have both stored genetic information and performed the basic operations of the cell, including RNA replication – it acted as both genotype and phenotype (Gilbert 1986). Extensive evidence has been found to support both the historical and functional claims of this hypothesis – modern life does appear to be descended from heavily RNA-based organisms, and RNA catalysts can perform many of the diverse functions performed by proteins in modern biology, including the replication of nucleic acids (Dworkin et al. 2003; Joyce 2002; Benner et al. 1989; Gesteland et al. 2006).

The history of life before its divergence from the LUCA, according to this model, can thus begin to be outlined (Fig. 1). Self-replicating RNA emerged on Earth by some mechanism and began to evolve. This replicating RNA diversified, assumed varied catalytic tasks, and formed a genome of significant complexity. Once RNA organisms invented a rudimentary ability to synthesize polypeptides, evolution led, eventually, to coded protein translation. The RNA world ended as proteins proved to be superior functional biopolymers and gradually took over most, though not all, of the catalytic tasks in the cell. DNA, a more chemically stable nucleic acid, evolved to replace RNA as genetic material in most organisms as well, though it is unclear whether this occurred before or after the invention of protein (Dworkin et al. 2003; Joyce 2002; Benner et al. 1989).

This entry will review the evidence for the existence of the RNA world and the current understanding of how it arose, evolved, and was replaced by modern DNA-RNA-protein life. The basic methodologies used to examine the RNA world will be briefly introduced, and then the

RNA World, Fig. 1 The postulated rise and fall of the RNA world during the evolution of life, from early self-replicating RNA to complex, RNA-controlled metabolism,

to the invention of translation, followed by diversification of all modern branches of life

current state of RNA world research will be reviewed in reverse chronology: beginning with evidence for the RNA world from modern biology and the transition into modern life, followed by efforts to understand how RNA life could function and evolve, and ending with the various possibilities by which RNA replication may have first emerged. Finally, different avenues of research poised to shed new light on the RNA world, and how such research may begin to intersect with other fields in the origin of life, will be reviewed.

Basic Methodology

Searching for “Molecular Fossils” in Modern Biology

Protein enzymes generally adopt more stably folded structures and a greater range of catalytic strategies than RNA enzymes (Cech 2009). This advantage would ensure that organisms that catalyzed protein translation would displace earlier RNA life via Darwinian evolution, in the process eliminating the less efficient ribozymes of the RNA world. Ancient paralogous protein sequences and folds indicate that a period of

rapid expansion of protein functions via duplication and specialization occurred prior to the common ancestor in all major aspects of cellular activity (Koonin 2003; Becerra et al. 2007; Wolf and Koonin 2007). Pathways must have existed to perform these tasks prior to the expansion of proteins, but no extant organism with these original pathways has been found.

Fortunately, biological evolution is notorious for leaving “frozen accidents” – traits present in modern organisms that appear unnecessary but arose in ancestral organisms in a different environmental context and became fixed in the organismal body plan, too critical to the functions of many other traits to tolerate subsequent modification. One oft-cited example is the recurrent laryngeal nerve in mammals that takes an extended and unnecessary detour down the neck and around the aorta to travel from the brain to the larynx, a relic of evolution of the nerve’s layout in fish, which have a circulatory system architecture quite different than that of mammals (Ridley 2004). The same could be expected to have occurred in the transition from RNA- to protein-based catalysis, with catalysts and reaction pathways originally evolved in RNA organisms conserved in modern

descendents, “molecular fossils” of the ancient RNA world. Biochemical and structural investigations of basic molecular and cellular activities, particularly in translation, have found a wealth of these relics.

In Vitro Evolution of RNA: Filling in the Gaps in the RNA “Fossil Record”

Barring the fortuitous discovery of a true “living fossil” of the RNA world, an RNA organism that has survived to the present day in some niche inimical or inaccessible to protein-based life, most of the content of the ancient RNA world genome will remain unknown. Directed in vitro evolution technologies offer an alternative: use the power of Darwinian evolution and modern synthetic biology to develop new ribozymes that “fill in the gaps” in the RNA genome by catalyzing reactions necessary to the RNA world (Joyce 2004, 2007; Müller 2006).

Darwinian evolution will act on any biopolymer that undergoes iterative cycles of sequence amplification, mutation, and selection for a particular function. All of these steps can be accomplished in vitro: PCR can amplify any DNA sequence, while other enzymes can be used to convert RNA into DNA and back again; a PCR protocol can be modified to introduce high rates of point mutations or recombination between distinct sequences; and selection of activity can involve any physical or chemical method that will selectively isolate RNA sequences with some desired feature, such as binding a specific ligand or catalyzing a particular reaction (Joyce 2004). Up to 10^{15} distinct sequences can undergo selection simultaneously. A tremendous number of functional RNA sequences have now been evolved, including both ligand-binding RNA ► [aptamers](#) and reaction-catalyzing ► [ribozymes](#). The range of activities discovered sheds light on a number of facets of the possible biochemistry performed in an RNA world.

The Emergence of the RNA World: Prebiotic Chemistry and Pre-RNA Life

The RNA world was originally proposed to solve a paradox of modern molecular biology, namely, the codependence of nucleic acids and proteins.

As such, the evidence for the existence of the RNA world comes from consideration of RNA relics in modern biology and the range of capabilities found in synthetic ribozymes. The emergence of the RNA world from chemical precursors, in contrast, has largely been a stumbling block; an RNA mononucleotide, let alone a polynucleotide, is a complex chemical that in modern biology is only synthesized by an extended, genetically encoded biochemical pathway. The proposal that prebiotic chemistry produced RNA does not follow from evidence in chemistry, but from evidence in biology that RNA life existed. The distinct views have been explained as the “molecular biologist’s dream and the prebiotic chemist’s nightmare” to emphasize the contrast between what appears necessary for the spontaneous emergence of RNA replication and what appears possible from prebiotic chemistry (Gesteland et al. 2006). A few alternative scenarios have been considered – the “RNA first” theory holds that some series of reactions, either fortuitous or inevitable, gave rise to replicating RNA, and from there, to life; a variety of related “genes first” theories posit that some simpler molecule, also capable of carrying genetic information, arose before RNA, forming a “pre-RNA world” that gave rise in turn to RNA; a number of “metabolism first” theories hold that simple metabolic systems could spontaneously self-organize on the early earth, forming life without genetic polymers, and only later invented RNA.

Key Research Findings

Translation Is Catalyzed by RNA

Translation of genetic information from nucleic acid to protein is the critical function that enabled the transition out of the RNA world. It is also the central biochemical pathway in life, and a large fraction of the inferred minimal genome of the LUCA consisted of the genes involved in translation (Wolf and Koonin 2007; Steitz and Moore 2003). As might be expected, “molecular fossils” of the RNA world have proven ubiquitous in translation and constitute the strongest evidence

for the historical existence of an RNA-based ancestor to modern life.

The most significant discovery is that the ► **ribosome**, arguably the most sophisticated nanomachine in biology, is a relic of the RNA world. Biochemical evidence and atomic-resolution structures of the ribosome show that both the mRNA (see ► **RNA**) decoding regions and the peptidyl transferase center that specifically catalyzes peptide bond formation between amino acids (protein synthesis) are surrounded by rRNA, not ribosomal proteins (Fig. 2) (Steitz and Moore 2003; Schmeing et al. 2005; Noller 2005). More succinctly, the ribosome is a ► **ribozyme**.

Proteins play important but largely ancillary roles in translating, folding, and stabilizing the ribosome and aiding in mRNA translocation (Steitz and Moore 2003; Noller 2005). A notable exception is that the charging of tRNA with amino acids, which establishes the genetic code, is catalyzed by the aminoacyl tRNA synthetase (aaRS) proteins. A few pieces of evidence suggest that

this was a late innovation. The aaRS proteins group into two distinct, unrelated folds and are paralogous to many other proteins with the same folds (Schimmel 2008; Goldman et al. 2010). Sequence and structural comparisons suggest that the aaRS forms are not ancestral, and translation was producing folded proteins before the aaRS proteins existed (Wolf and Koonin 2007). Some other mechanism of tRNA aminoacylation must have preceded the modern, protein-catalyzed form. It seems significant that the 3'-end of tRNA contributes to catalysis both in the peptidyl transferase center of the ribosome and the acylation site of the aaRS proteins (Schmeing et al. 2005; Hagiwara et al. 2010). Generation of this 3'-end is itself catalyzed by RNase P, which is a true ribozyme, capable of activity in the complete absence of proteins (Scott 2007). A great deal of the roles of tRNA and the aaRS proteins remains open to investigation, but the modern form of this pathway does seem to derive from one in which RNA played a more central role.

RNA World, Fig. 2 The structure of the bacterial 50S ribosomal subunit, composed of ribosomal RNA (gray) and the ribosomal proteins (blue). A transition state analogue (red) is bound to the peptidyl transferase center. Note that the center is composed entirely of ribosomal RNA, while the ribosomal proteins primarily decorate the exterior (PDB ID code 1VQP). (Schmeing et al. 2005)

RNA Processing Is Catalyzed by RNA

Although translation has proven the most fertile ground for discovering RNA relics, other biochemical pathways are also informative. RNA is extensively involved in its own splicing, including the self-splicing Groups I and II ► **introns** and eukaryotic introns spliced by the spliceosome. Like RNase P, self-splicing introns are ribozymes that can function in the complete absence of proteins, though in both specific proteins aid in folding and stabilizing the ribozymes (Scott 2007; Toor et al. 2008). Eukaryotic introns are somewhat more complex, as they are spliced by a multi-subunit RNA-protein (RNP) complex called the spliceosome. One of the small nuclear RNAs (snRNAs) central to its function, the U6 snRNA, has sequence and structural similarity to the Group II intron catalytic core, suggesting that the spliceosome evolved from a ribozyme (Roy and Gilbert 2006; Rodríguez-Trelles et al. 2006).

However, the case for the origin of these ribozymes in the RNA world is not as certain as for the ribosome, as such activity was not necessarily present in an RNA organism. Different theories have introns developing before the origin of

translation, soon afterward, or even after the divergence of the three domains of life from the LUCA (Roy and Gilbert 2006; Rodríguez-Trelles et al. 2006). Regardless of their historical origin, the activities of self-splicing introns and RNase P prove that RNA can function as an enzyme independent of protein and specifically catalyze reactions similar to the basic chemistry of RNA polymer synthesis and replication (Gilbert 1986). Taken together with evidence that the ribosome is a ribozyme, both peptide and RNA syntheses are activities plausibly carried out by naturally occurring ribozymes.

The last few decades have unveiled a wealth of nonprotein-coding RNA with biological activity, to such an extent that the term “RNA world” is now used both to refer to the ancestral role of RNA in the origin of life and the extensive role of RNA in modern biology (Sharp 2009). Although fascinating biologically, it is important to note that there is often little evidence that these RNAs originated in an ancestral RNA world and may have evolved in modern biology to perform tasks for which RNA is intrinsically suited. Still, the diversity of RNA functions indicates the RNA world could have possessed considerable complexity. Moreover, the diverse manners in which RNA and protein have been found to interact may represent a series of “transitional forms” showing that during the early evolution of translation, proteins evolved not as stand-alone catalysts but to assist the activity and folding of existing ribozymes (Cech 2009).

Remnants of the RNA World in Modern Metabolism

As with RNA macromolecules, “molecular fossils” of RNA metabolism could have been passed on to modern organisms. Many biological cofactors are ribo ► [nucleotides](#), derived from ribonucleotide substituents, or incorporate ribonucleotide moieties (Fig. 3). Most of these cofactors are used in metabolism across all domains of life, for energy transfer (ATP), redox reactions (FAD, NAD⁺), and methyl group transfer (SAM), among other activities, suggesting that they arose very early in the history of life. A ribonucleoside or nucleobase “handle” could

enable ribozyme catalysts to more readily bind the cofactors non-covalently or have them directly attached covalently (Joyce 2002; Benner et al. 1989). Similarly, charged tRNAs are used in metabolic pathways as the source of amino acids for the synthesis of other amino acids, cross-linking of the bacterial peptidoglycan cell wall, and even the synthesis of tetrapyrroles (Francklyn and Minajigi 2010). It is not clear why free amino acids are not used directly, unless the pathway evolved in an era where RNA played a more active role in metabolism.

Separately, a variety of metabolic pathways, including the synthesis of imidazole, thymine, and deoxyribonucleotides, proceed through ribonucleotide intermediates. This does not seem necessary from chemical first principles, but could be explained if these pathways originated in RNA-based organisms where the metabolic synthesis of RNA mononucleotides had already evolved (Joyce 2002). The synthesis of DNA monomers may also indicate whether DNA genomes evolved before or after translation. RNA may be incapable of stably generating free radicals for the reduction of ribose to deoxyribose, and thus, this reaction could not have occurred until proteins emerged (Joyce 2002).

RNA Functionality and Evolvability

Moving beyond functions still performed by RNA in modern biology, in vitro evolution of RNA ► [aptamers](#) and ► [ribozymes](#) has begun to survey the capacity of RNA to perform a variety of functions. RNA sequence space, the set of all possible RNA sequences, has proven to be rich in the distribution of structured RNA and enzymatic activity. Most ribozyme families known today have been evolved de novo, by beginning in vitro evolution with populations of randomly generated RNA sequences. Ribozymes range in length from tens to hundreds of nucleotides and in catalytic rate enhancement of 10–10⁹-fold. Both theoretical and experimental efforts have demonstrated that RNA can explore multiple sequences in the context of the same structure and access new structures by only a few mutations, proving adept at evolving new function through multiple mechanisms. Once the RNA world got started, it

RNA World, Fig. 3 Metabolic cofactors found in all domains of life, used as an energy source (ATP), redox reagents (FAD and NAD⁺), an acyl carrier (CoA), or a

methyl group donor (SAM). All contain an adenosine moiety that does not directly contribute to their chemical function

could have evolved quite quickly (Gesteland et al. 2006; Joyce 2004; Müller 2006; Chen et al. 2007).

In Vitro Evolution of RNA: Translation

The synthesis of protein during translation involves three chemical steps starting from free amino acids: amino acid adenylation, aminoacylation of tRNA, and peptide bond formation. Simple ribozymes discovered via in vitro evolution catalyze each of these reactions. Ribozymes that charge RNA with amino acids, the function of modern aaRS proteins, can be extremely efficient catalysts, occasionally achieving rates greater than the aaRS proteins (Chen et al. 2007). One such ribozyme, evolved to

aminoacylate the acceptor stems of natural tRNA, can substitute for aaRS enzymes in an in vitro translation system, demonstrating the potential functionality of primordial RNA-only translation (Ohuchi et al. 2007). Another ribozyme is the smallest yet discovered, a five-nucleotide RNA acting on a four-nucleotide substrate. It catalyzes both aminoacylation of the substrate from aminoacyl adenylate and peptide synthesis using additional adenylates, suggesting that peptide synthesis could have evolved very early in the RNA world (Turk et al. 2010).

As of yet, no ribozyme has been found to catalyze peptide synthesis by the same mechanism used in the ribosome, via two aminoacylated

RNAs, nor to catalyze coded peptide synthesis, where a peptide of defined sequence is synthesized specifically using an RNA sequence guide (Chen et al. 2007). The simplicity with which nucleic acids can be used to template a variety of chemical reactions suggests that the development of this particular reaction may simply await an appropriately designed selection experiment (Gartner and Liu 2001). More generally, although all the individual reactions of translation have been shown to be catalyzed by ribozymes, no ribozyme or set of ribozymes have been shown to catalyze the reactions in series, producing polypeptides from amino acid and ATP as starting materials. Many aspects of in vitro evolution are still quite rudimentary, and beyond this particular reaction, no set of ribozymes have yet been combined, via rational design or evolution, to catalyze an extended multienzyme pathway. Efforts to achieve such pathways may be one of the most interesting areas to focus in vitro evolution research in the future.

In Vitro Evolution of RNA: Metabolism

Synthesis of ribonucleotides in modern biology proceeds through a number of distinct pathways, which may themselves differ from the mechanisms used prior to translation. However, ribozymes can perform a number of chemical steps necessary to the synthesis of ribonucleotides from simple precursors. These steps include aldol condensation, a possible pathway to synthesize sugars including ribose; glycosidic bond formation between activated ribose and either purines or pyrimidines to form ribonucleosides; and phosphorylation of the 5'-end of a ribonucleoside with ATP, yielding a ribonucleotide (Chen et al. 2007).

In vitro selected ribozymes can also use many modern metabolic cofactors. RNA aptamers have been found that bind nearly any cofactor, and ribozymes have been evolved to attach NAD^+ , S-adenosylmethionine, FAD, and CoA to another RNA. Ribozymes can use NAD^+ to dehydrogenate a benzyl alcohol, ATP to phosphorylate or adenylate other nucleotides or amino acids, and acyl-coenzyme A for both aminoacylation and the Claisen condensation (Chen et al. 2007). In summary, RNA is adept at binding, covalently

incorporating, and using many metabolic cofactors. Unfortunately, as with translation, experiments have focused on the capacity of RNA to perform basic reactions in any format, rather than in formats conducive to forming extended biochemical reaction pathways. The evolution of complex systems of ribozymes remains largely unexplored.

In Vitro Evolution of RNA: Replication

The most important activity in an RNA organism would be RNA replication. Although replication may have begun spontaneously, RNA catalysis would be necessary to replicate a complex RNA genome. A ribozyme capable of self-sustained replication, given a constant supply of substrates, could grow indefinitely, and errors created during replication could have led to the generation of heritable mutations and thus potentially Darwinian evolution. If life is defined as a self-sustained chemical reaction capable of Darwinian evolution, a system of replicating RNA could qualify as one of the simplest imaginable forms of life.

In nature, replication of nucleic acids is achieved by template-directed polymerization of mononucleotide 5'-triphosphates (NTPs), in which the 3'-hydroxyl group of a polynucleotide attacks the α -phosphate of an NTP, releasing pyrophosphate and forming a 3'-5' phosphodiester bond. The first ribozymes evolved in vitro to catalyze the same chemistry were **ligases** rather than polymerases, using a polynucleotide 5'-triphosphate rather than a mononucleotide. This is an easier reaction for a ribozyme to catalyze, as the assembly of both the 3'-hydroxyl and 5'-triphosphate oligonucleotides on a template is spontaneous. Six unrelated ribozyme ligases have been evolved, ranging in catalytic rates from 1 h^{-1} to 1 s^{-1} , and a few other ribozymes perform similar ligations with different regiochemistry or leaving groups. The basic chemistry of template-directed RNA synthesis is apparently readily catalyzed by ribozymes (Joyce 2004).

An interesting convergence can be observed for protein and RNA catalysts of RNA synthesis. Ribozyme ligases depend on divalent cations, typically Mg^{2+} , for activity, as do protein-based polymerases. The atomic-resolution crystal structures of an RNA polymerase protein enzyme, the self-splicing Group

I intron ribozyme, and two distinct synthetic ribozyme ligases can be compared for more details (Fig. 4) (Shechner et al. 2009; Stahley and Strobel 2005; Yin and Steitz 2004). In every case, the enzyme uses a magnesium ion to activate the 3'-hydroxyl nucleophile, stabilize the negative charge on the oxygen of the phosphate electrophile, and coordinate the two groups in a geometry conducive to nucleophilic attack. None of these enzymes are homologous, indicating that magnesium-catalyzed phosphodiester bond transfer is a simple and general catalytic mechanism. The fact that the phosphate backbone of RNA can

readily coordinate magnesium ions may explain the facility with which RNA can evolve ligase activity.

A great deal of effort has been expended attempting to convert ribozyme ligases into more general RNA polymerases. One ligase, the very active and complex Class I ligase, has undergone extensive further evolution as a general RNA polymerase (Fig. 5a). The results are impressive: the most evolved variant can, on some templates, polymerize 20 template-directed ► [nucleotide](#) additions over the course of a day, with an accuracy of 97% per base (Zaher and Unrau 2007;

RNA World, Fig. 4 Natural and synthetic enzymes that catalyze phosphodiester bond formation between RNA molecules. Shown are the active sites of (a) T7 RNA polymerase (PDB ID: 1S76), a natural protein enzyme; (b) *Azoarcus* Group I self-splicing intron (PDB ID: 1ZZN), a natural ribozyme; (c) the L1 ligase (PDB ID: 20 IU), a synthetic ribozyme; and (d) the Class I ligase (PDB ID: 3HHN), also a synthetic ribozyme. (a) and (b) contain unreacted substrates, and (c) and (d) contain the

reaction product. The catalytic magnesium ion is shown as a red sphere in each image, with contacts between the metal, 3'-OH nucleophile, and the α -phosphate electrophile shown as dashed lines. In (d), a magnesium ion was not visible in the crystal, but its position could be inferred from biochemical experiments. (Robertson and Scott 2007; Shechner et al. 2009; Stahley and Strobel 2005; Yin and Steitz 2004)

RNA World, Fig. 5 Two approaches to RNA replication. (a) The general polymerase ribozyme can synthesize RNA of arbitrary sequence given a complementary template RNA. However, low substrate affinity and poor processivity prevent it from synthesizing more than 20 nucleotides in 24 h (Johnston et al. 2001). (b) The cross-catalytic

replicator consists of a pair of ligase ribozymes that synthesize each other from smaller substrates. The replicator can only copy itself, not an arbitrary RNA sequence, but populations of such replicators have been shown to evolve. (Lincoln and Joyce 2009)

R

Johnston et al. 2001). Nevertheless, to replicate RNA of its own length, the polymerase would need to improve activity by more than tenfold.

Further evolution may be hampered by the original evolution of the ligase fold as a single-turnover enzyme. The main kinetic limitations of the polymerase do not involve maximal activity, but rather extremely low-affinity binding to its substrate RNA and poor processivity, adding only one to three nucleotides before it releases the substrate and must rebind. Novel selections, either on this polymerase or de novo RNA populations, will need to focus on enforcing

polymerization in a format more conducive to RNA replication (Joyce 2007).

Recently, a simpler form of replication has been achieved using a cross-catalytic replicator made of a pair of ligase ribozymes that synthesize each other from smaller substrate oligonucleotides (Fig. 5b) (Lincoln and Joyce 2009). Fed a constant supply of substrates, the replicator grows exponentially and indefinitely, the first experimental example of self-sustained RNA replication. Moreover, the system appears capable of at least rudimentary Darwinian evolution: fed a variety of substrates, errors in substrate selection by existing replicators generate novel replicators that

“breed true,” replicating themselves rather than the original “parent” replicator. Some of these novel replicators collectively grow more efficiently than the “parent” replicators, eventually taking over the population.

The complexity of the oligonucleotide substrates, the “feedstock,” for these replicators is quite high, and thus, this system cannot plausibly explain the origin of self-replicating RNA. It does, however, demonstrate how very simple ribozyme systems can achieve self-replication, and it seems likely that many such systems can be developed. These replicators are not capable of general replication of any RNA and thus could not, as currently constituted, replicate other RNA genes that might have contributed to metabolism or other activities critical to a cell. Although the replicators evolve, it remains to be seen if they can evolve novel functions, rather than simply improve the existing replication activity. If such capacity for novel evolution is shown, however, the replicator system may well be a form of independent RNA life, capable of bootstrapping itself into higher levels of genetic and functional complexity.

Models of Evolution in Self-Replicating RNA Systems

Theoretical considerations may already suggest how such systems evolve. Primitive replicating systems might have extremely high mutation rates, which provide both opportunities and limitations. With high replication error rates, a population continuously samples all possible nearby variants and thus can evolve rapidly to new genotypes in the presence of changing selection pressures. When mutation rates are too high, however, selection cannot maintain a distinct genotype and the population will fail to evolve. In its simplest form, this limitation requires that genome size must remain less than the inverse of the error rate, and this holds true for genomes ranging in size from small viruses to complex eukaryotes. For a simple replicating RNA molecule, increases in complexity depend on the capacity to improve the accuracy of replication (Joyce 2002; Szathmáry and Maynard Smith 1997).

During the early evolution of life, individual self-replicating RNA species would need to

evolve into the more complex genomes of the modern cell, with ribozymes performing varied non-replicative tasks that aided growth of the cell but did not contribute directly to their own replication. The solution arrived at in biology is cellular compartmentalization. By isolation from the external environment, the benefits of metabolism and replication accrue only to the genes contained within the cell. A number of other solutions, however, may be plausible and have been investigated: including assembly of distinct ribozymes into larger ribosome-like complexes and restriction to two-dimensional surfaces or microscopic pores in minerals (Szathmáry and Maynard Smith 1997). As experimental systems of self-replicating RNA become more sophisticated, it should be possible to test these models directly.

RNA Replication Before Ribozymes

Ribozyme-mediated replication and metabolism could not have emerged without some mechanism of forming RNA polynucleotides. With the absence of the possibility that some other forms of life existed before RNA, these RNA polymers must have been formed by ► [prebiotic chemistry](#). Unfortunately, forming RNA polymers or even activated monomers has proven exceptionally difficult. The prebiotic synthesis of ribonucleotides is discussed below, but even assuming that they can be produced, their polymerization remains a significant hurdle. Spontaneous reactions with 5′-triphosphates are most likely not feasible, as the triphosphate, although high in energy, is kinetically stable – templated ligation of RNA oligomers is extraordinarily slow, comparable to the rates of RNA hydrolysis (Gesteland et al. 2006).

Monomers activated with other leaving groups, such as mononucleotide 5′-phosphoimidazolides, can polymerize spontaneously, and the presence of an RNA template can in some cases direct the polymerization of the complementary sequence. However, both 2′–5′ and 3′–5′ regioisomers of RNA are formed, and adenosine and uridine monomers do not polymerize well. Solutions to these problems exist: ► [montmorillonite](#) clays can accelerate and increase the regiospecificity of untemplated polymerization, producing polynucleotides in excess of 40 bases.

Polymerization with base intercalators or in the eutectic phase of water ice accelerates ► [template-directed polymerization](#), including that of adenosine and uridine monomers. Still, no reaction scheme has yet shown robust template-directed RNA synthesis (Gesteland et al. 2006).

Non-prebiotic RNA analogues can achieve considerably better results, with the most advanced system capable of polymerizing mixed sequences from a template, but currently limited by accumulation of mutations that inhibit further polymerization (Schrum et al. 2009). Theoretical treatments suggest that Darwinian evolution could arise rapidly once accurate replication is achieved (Nowak and Ohtsuki 2008). If progress continues, this system may represent a much simpler form of nucleic acid replication relative to the ribozyme cross-replicator and may reveal how Darwinian evolution can emerge from extraordinarily simple, uncatalyzed chemical reactions.

Emergence of Ribonucleotides

The demonstration of a plausible, prebiotic route to ribonucleotide monomers has proven to be an extraordinarily difficult task. Prebiotic chemistry is a broad field, and diverse reactions have been found that yield components of ribonucleic acid. Three general conclusions can be drawn from the data thus far collected (Joyce 2002; Gesteland et al. 2006):

1. The components of ribonucleotides could have been available on the early Earth. Sugar-like molecules, purines, and pyrimidines have all been found in varying quantities in meteorites, and plausible prebiotic syntheses have been demonstrated for all three. Both phosphate and inorganic polyphosphates would also have been present on the early Earth.
2. The synthesis of ribose and the natural nucleobases to high purity relative to other analogues is much more difficult. The autocatalytic formose reaction produces ribose in very low yields relative to other sugars, though ribose can be favored by interaction with borate minerals, reaction with cyanamide and selective crystallization, or selective diffusion across prebiotic fatty acid membranes. Besides

the synthesis of adenine as a major product from cyanide polymerization, similar problems exist for the nucleobases.

3. The synthesis of ribo► [nucleosides](#) and ribonucleotides from these constituents is even more difficult. The synthesis of purine ribonucleosides from a purine and ribose is inefficient and yields a variety of isomers and side products, while the synthesis of pyrimidine ribonucleosides directly from the biological pyrimidines and ribose appears even more difficult. Phosphorylation can occur under some extreme conditions, but generally produces a mixture of multiply phosphorylated products.

Given these difficulties, a route to relatively pure, activated mononucleotides seems implausible. However, a recent approach may have revitalized the field by integrating the chemistries of nucleobase and sugar synthesis, and phosphorylation, to produce the two biological pyrimidine ribonucleotides (Fig. 6) (Powner et al. 2009). Cytidine and uridine 2',3'-cyclic phosphates are produced in a series of reactions that completely avoid the intermediate synthesis of free ribose or pyrimidines, mixing reactions between the very distinct chemistries of nucleobase and sugar synthesis. Further progress will require demonstration of similar routes to the purine ribonucleotides as well as plausible mechanisms for the isolation of the starting materials for subsequent reactions, neither small tasks. The problem of a plausible polymerization mechanisms, described previously, also remains. Still, the possibility that a route to the origin of RNA life from prebiotic chemistry can be found has improved significantly.

Life Before RNA

Ribonucleotides are complex molecules that are biosynthesized by a series of genetically encoded metabolic pathways. It may be that RNA is so complex that it can only be plausibly synthesized by the metabolism of a living organism. If so, it follows that RNA itself was not the first form of life but rather a product of it, just as protein macromolecules were invented by RNA-based life. The appeal of this idea, of course, is that the

RNA World, Fig. 6 Two routes to the prebiotic synthesis of pyrimidine nucleosides from simple starting materials. The top route attempts to synthesize cytosine and ribose separately. Reactions between the biological pyrimidines and ribose to form ribonucleosides have thus far proven unsuccessful. The bottom route uses a series of coordinated reactions in which pyrimidines and ribose do not form separately, and incorporation of phosphate yields the final product, cytosine 2', 3' cyclic phosphate (as well as uridine 2', 3' cyclic phosphate after UV irradiation, a step not shown). (Powner et al. 2009)

difficulty of synthesizing RNA prebiotically is avoided. Instead, an entirely distinct form of life must be described and shown to arise more readily than RNA life.

One potential candidate would be another biopolymer, particularly one with a capacity, like RNA, to undergo templated replication. If such a

polymer also proved more amenable to spontaneous synthesis, it could very well have arisen first, only later giving way to RNA due to, perhaps, the superior activity of ribozymes. Investigation of nucleic acid analogues has demonstrated that the ribose-phosphate backbone can be changed substantially while retaining the ability to base-pair with a complementary sequence and that a whole family of nucleic acid-like molecules can function as genetic polymers (Eschenmoser 1999; Nielsen 2007). The most notable of these, from an origin's perspective, have been threose nucleic acid (TNA) and peptide nucleic acid (PNA) (Gesteland et al. 2006). Threose and amino acids may have formed more abundantly on the early Earth than ribose, and both polymers are more stable than RNA. Still the prebiotic synthesis and polymerization of these analogues, or others, remain to be demonstrated.

More arcane possibilities have also been considered. The templated growth of clay minerals may be capable of some rudimentary form of replication and evolution, and the fact that such minerals are known to catalyze a variety of prebiotically relevant reactions, including RNA polymer synthesis, offers a potential route for the transition into an RNA world (Joyce 2002). Many other scenarios propose that simple autocatalytic reaction cycles involving small organic molecules could spontaneously self-organize, grow, and even evolve (Segre 2000; Copley et al. 2007). The plausibility that such cycles could form, and their ability to evolve, remains disputed (Orgel 2008). Experimental demonstration that such a cycle can replicate independently of genetically encoded catalysis would be a tremendous breakthrough, but, as with many other scenarios for the origin of life, experimental demonstrations are lacking.

Future Directions

A Concerted Pathway to Nucleic Acid Polymers

The strong evidence for the existence of the RNA world from modern biology suggests that a route to RNA polymers on the early Earth exists, either

directly or via the origin and evolution of some even more primitive form of life. However, there is no clear evidence as to what that route was. Distinct theories for the origin of life may very well outnumber researchers, but viable experimental models most certainly do not. Addressing this imbalance will be critical to further progress.

Significant advances have been made in a number of related fields. Mechanisms for the origin of homochirality; the growth, division, and competition between prebiotic vesicles; and the concentration of prebiotic building blocks from dilute solutions have all been demonstrated experimentally recently (Budin and Szostak 2010). The potential to combine these mechanisms and integrate them with experimental models of RNA synthesis may yield robust experimental frameworks for the origin of living systems from simple physicochemical mechanisms.

Self-Replicating Darwinian Systems

At least one system of RNA self-replication has been developed and shown to undergo limited Darwinian evolution. Other systems offering simpler and more complex forms of replication may be forthcoming. Further development of these systems could eventually produce synthetic nucleic acid-based life and open up new avenues to explore the RNA world model by direct observation. The propagation of these replicators under diverse experimental conditions could reveal how RNA life adapts and evolves. Of particular interest will be the exploration of how RNA genomes increase in complexity and the mechanisms by which new ribozymes, and the chemical pathways they control, evolve. It is unclear where such investigations can lead, but they offer the best methods available to understand the biochemistry of life's earliest ancestors.

The End of the RNA World and Its Legacy in Modern Biology

The vestiges of RNA ancestry in modern organisms are extensive. Research is now beginning to focus on using such evidence to investigate how modern biology evolved from simpler precursors. Knowledge of the modern form of translation and the interactions between RNA and protein, for

instance, may reveal how and why coded protein translation originally evolved. The earliest roles of polypeptides may have been as structural cofactors to RNA, a role still seen in many ribonucleoproteins, including the ribosome (Noller 2004). Structural evidence suggests that the peptidyl transferase center, and not the mRNA decoding regions, may be the most ancient part of the ribosome and could have existed originally as a dimerized ribozyme only 150 nucleotides long (Bokov and Steinberg 2009; Agmon et al. 2009). Similarly, the tRNA acceptor stem, to which amino acids are attached, may predate and can function independently of the tRNA anticodon stem used to decode mRNA (Schimmel and Ribas De Pouplana 1995). Early peptide synthesis may well have involved a simple peptidyl transferase ribozyme that used a series of tRNA-like substrates to synthesize polypeptides of predefined or even random sequence. It remains to be seen if more evidence from modern biology or in vitro evolution experiments can shed light on the origin of translation.

More broadly, novel roles for RNA in biology are being discovered at an incredible rate, and there remain many broad classes of nonprotein-coding RNA whose function is still uncharacterized. Small RNA molecules covalently attached to acyl-CoA and NAD⁺ cofactors have been identified in bacteria. Their significance remains unknown, but given the proposal that nucleotide-tagged cofactors originated in the RNA world, the possibility that these RNA molecules represent relics of ancient ribozyme-controlled metabolism cannot be discounted (Kowtoniuk et al. 2009; Chen et al. 2009). Other classes of larger RNAs with unknown function have also been catalogued (Weinberg et al. 2009). The activity of these RNAs will no doubt be fascinating, and some may very well prove to have an origin in the ancient RNA world.

Roche Limit

Jérôme Perez
Applied Mathematics Laboratory, ENSTA
ParisTech, Paris Cedex 15, France

Keywords

Gravitation · Stability · Tidal effect

Synonyms

Roche radius

Definition

The Roche limit is the orbital distance below which a satellite is tidally destroyed by the body around which it is orbiting. Édouard Roche is the French astronomer who first calculated this theoretical limit in 1848.

Overview

Tidal forces are simply the difference in gravitational forces felt by different parts of an extended body. The force of gravity felt by a satellite orbiting a primary body (e.g., by a moon orbiting a planet or a planet orbiting a star) decreases as the inverse square of the orbital distance such that different parts of the satellite feel different gravitational forces. From the point of view of the satellite, this results in a stretching because the side that is closest to the primary body is pulled more strongly than the side farthest from the primary (see Fig. 1).

This tidal stretching acts to elongate the satellite, increasing the distance between the opposite sides of the body and therefore increasing the strength of the tidal force. This stretching is counteracted by the satellite's self-gravity and internal cohesive forces. The Roche limit is simply the distance below which the tidal stretching overwhelms the satellite's self-gravity and tears the satellite apart. A simple formula for the Roche limit R_ℓ is

$$R_\ell \simeq \kappa \left(\frac{\rho_p}{\rho_s} \right)^{1/3},$$

where ρ_p and ρ_s represent the mass density of the primary body and the satellite, respectively. The

Roche Limit, Fig. 1 Tidal forces, as seen in the absolute reference frame (*top*) and in the body's reference frame (*bottom*)

numerical factor κ is of order unity and quantifies the satellites' internal cohesion (i.e., κ depends on the nature of the satellite).

Most of Saturn's rings are partially located inside the Roche limit of Saturn, which explains why they cannot accumulate into a larger body. The Roche limit is not to be confused with the Roche radius, usually referred to as the Hill radius.

Rock

Nicholas Arndt
ISterre, University Grenoble Alpes, Grenoble, France

Definition

Rock is the naturally occurring solid material of the Earth and other planetary bodies such as rocky planets, ► [asteroids](#), and ► [comets](#). Its composition is variable, depending on its mode of formation and the types of constituent minerals and organic substances. There are three main types of rock: ► [igneous rocks](#), which form by crystallization of magmas, either slowly and deep within the crust (plutonic rocks) or by rapid cooling at a planetary surface (volcanic rocks); ► [sedimentary rocks](#), which either result from the crystallization of chemically precipitated substances (on Earth commonly biologically mediated), the deposition and cementation of detrital grains, or the lithification of organic substances; and ► [metamorphic rocks](#), which are produced when the other two types of rocks are subjected to elevated temperatures and pressures. These three types of rocks are part of a “rock cycle” in which the main drive is ► [plate tectonics](#).

Rodinia

Nicholas Arndt
Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Definition

Rodinia is one of the oldest known ► [supercontinents](#). It existed in the Neoproterozoic, from about 1100 to 750 Ma; it comprises the oldest portions of almost all the present-day landmasses. The North American Craton formed its core, flanked by fragments now present in northern Europe, Africa, South America, India, and Antarctica. It was probably centered in the southern hemisphere, and since it persisted through the period of extreme cold known as the ► [Snowball Earth](#) of the Cryogenian period, large parts of it were probably covered by ice caps. It has been proposed that the ecosphere turnover and bioradiation events in the Ediacarian and in the Cambrian could have been triggered by the consequences of the Rodinia breakup to Earth's atmosphere and hydrosphere.

Spacecraft

Definition

The Rosetta mission was a Planetary Cornerstone Mission in the European Space Agency's program Horizon 2000. It had a rendezvous in August 2014 with the →comet →67P/Churyumov-Gerasimenko to study its nucleus chemical and physical properties, and the development of its atmosphere as the comet approaches the Sun. Rosetta followed the comet for about 2 years before and after its perihelion in August 2015. The mission was terminated with a controlled crash on the comet's nucleus on September 30, 2016. Rosetta spacecraft was carrying an instrumented lander called →Philae delivered to the nucleus on November 12, 2014. On its way to the comet, Rosetta flew by asteroids 2867 →Steins and 21 →Lutetia.

Overview

Rosetta was the first space mission whose goal was to land on a cometary nucleus and follow a comet for about 2 years. It was first conceived to explore comet 46P/Wirtanen. However, because of a failure of an Ariane 5 rocket in December 2002, the mission was postponed, and a new target had to be chosen: →67P/Churyumov-Gerasimenko (hereafter 67P). Rosetta was finally launched by an Ariane 5 G+ from Kourou (French Guyana) on March 2, 2004. Its journey toward the comet was 10 years long and employed four planetary gravity-assist maneuvers (Earth-Mars-Earth-Earth). Rosetta reached its target in August 2014

and released →Philae that landed on the nucleus on November 12, 2014, at about 3 AU from the Sun. Then, Rosetta escorted the comet before and after its perihelion in August 2015 (at 1.3 AU from the Sun), witnessing the comet’s increasing activity as it gets closer to the Sun and its decrease when the comet moved away on its orbit. The end of the nominal mission was originally scheduled in December 2015. However, ESA decided to continue the mission until the spacecraft was too far away from the Sun to receive sufficient energy from its solar panels to be operated. The mission was terminated on September 30, 2016, with a controlled crash of the spacecraft on the nucleus, allowing last measurements in close vicinity of the nucleus. Important dates of the Rosetta mission are given in Table 1.

The science objectives of the mission were: (1) a global characterization of the nucleus (dynamic properties, surface morphology, and composition); (2) the determination of the chemical, mineral, and isotopic compositions of volatiles and refractories in a nucleus, as well as the links between the gaseous and the solid phases; (3) the study of the development of cometary activity and the processes in the surface layer of the nucleus and the inner coma (dust/gas interaction); and (4) the study of the evolution of the interaction region of the solar wind and the outgassing comet during perihelion approach.

12/2015	Planned end of the nominal mission
30/09/2016	End of mission

The mission’s name refers to the Rosetta stone that gave Champollion a crucial clue to understanding Egyptian hieroglyphs. The lander was called Philae, following the name of the island on which an obelisk was found. Its association with the Rosetta stone helped Champollion in his discovery. As the Rosetta Stone provided the key to an ancient civilization, the Rosetta instruments were designed to unlock the information kept in the oldest building blocks of our solar system: the comets.

Basic Methodology

Rosetta’s design is based on a central cuboid structure (2.8 × 2.1 × 2.0 m). The total launch mass is 2900 kg, including Philae (100 kg), 165 kg of scientific payload, and 1720 kg of propellant. The nominal solar array output was 850 W at 3.4 AU.

Rosetta payload consists of 12 scientific instruments onboard the orbiter and 10 on the surface science package (Philae) (Table 2). During the 2 years of the mission, the spacecraft has performed a complex navigation program in the vicinity of comet 67P in order to: (1) fulfill the science objectives of the mission by enabling operation of all instruments that required various orientations and distances from the nucleus, but also to (2) keep the spacecraft at a safe distance in order to avoid to be damaged by the dust particles ejected from the nucleus, especially during the period of high activity of the comet around perihelion.

Key Research Findings

The Rosetta mission has produced a considerable number of results showing that the comet 67P nucleus is a binary object formed by the low-speed collision of two distinct bodies during the early stages of the formation of the solar system (Fornasier et al. 2021; Massironi et al. 2015). It is made of two parts of about 4.10 × 3.52 × 1.63 km

in size for the larger lobe and $2.50 \times 2.14 \times 1.64$ km for the smaller one (Jorda et al. 2016). Its mass is 1.0×10^{13} kg with a density of about 0.5 g cm^{-3} , pointing to a rather large porosity of about 70–75% (Jorda et al. 2016). On a

microscopic scale, the cometary matter is built on multiscale particles resulting from hierarchical accretion. The activity of the nucleus is characterized by continuous degassing, which generates a diffuse, permanent coma marked by jets visible for hours emitted by regions rich in CO₂ or H₂O frost. This degassing leads to progressive erosion seen through collapsing cliffs or the appearance of fine lines in smooth areas. These processes remain superficial because the interior of the core is insulated from solar heating by its low thermal inertia. The surface is a succession of terrains with pits, depressions, boulders, and smooth areas. The nucleus rotates in about 12.4 h. It has been inferred from the various instruments of Rosetta that the nucleus refractory to ice ratio bulk composition could range from 3 to 6, with higher values being possible (Choukroun et al. 2020). However, high uncertainty remains attached to this value.

In this entry, the focus is given to results that have an astrobiological relevance. They relate to the organic content of the nucleus and the nature of volatile elements and water that may have contributed to the building of Earth’s atmosphere and oceans.

Regarding the composition of the atmosphere of the comet and the inventory of the diversity of its molecular composition, the ROSINA mass spectrometer has identified in the gaseous phase a wide variety of volatiles compounds, adding dozens of molecules (especially organic) to the list of already known compounds (Rubin et al. 2019). Among them, the detection of →glycine, the simplest amino acid, must be noted (Altwegg et al. 2016). This is a confirmation of its presence that was shown in the cometary samples returned to Earth with the →Stardust mission (Elsila et al. 2009), but at that time it was unclear whether glycine was indigenous from the comet →Wild 2 or synthesized from precursors during the analytical procedure that leads to its detection in Stardust samples. Although the presence of this relatively simple compound can be explained by the photochemistry of molecules such as CO₂ and CH₃–NH₂ in cometary ices (Bossa et al. 2009), and that chemistry from amino acids to the origin

of life certainly involved many complex and unknown steps, its detection contributes to strengthening the idea that comets could bring to Earth molecules involved in the processes that led to the emergence of life. Surprisingly, glycine was detected in the gaseous phase with ROSINA, and not, considering the low volatility of this molecule, in the solid fraction of dust particles by the COSIMA mass spectrometer. This has been interpreted by the fact that glycine was synthesized in the water ice and released into the gaseous phase when it sublimated from dust particles within the first kilometers after being lifted from the nucleus (Hadravský et al. 2019). Furthermore, ammonium salts, classical organic reagents used in the laboratory in studies related to prebiotic chemistry, have also been detected with ROSINA (Altwegg et al. 2020).

One of the mission's most eagerly awaited measurements was the D/H ratio in water. Taking into account the orbit of 67P and the measurements made in other comets, especially those from the Jupiter family like the target of Rosetta, a value close to that of the terrestrial oceans (1.5×10^{-4}) was expected. However, Rosetta revealed, with the ROSINA instrument, the highest ratio for a comet to date ($5.3 \pm 0.7 \times 10^{-4}$) (Altwegg et al. 2014). The statistics remain too weak among comets to conclude on the cometary contribution of terrestrial water. However, the isotopic measurements of xenon offer better constraints. The isotopic anomaly of the xenon of the terrestrial atmosphere (called U-Xenon), with regard to the measurements Rosetta, can only be explained if the composition of the early Earth's atmosphere was 20% cometary and 80% meteoritic ($\rightarrow$ chondrite) (Marty et al. 2017). 67P-type comets would therefore have contributed only slightly to the formation of the Earth's oceans and atmosphere, but 67P being the only comet in which xenon has been measured, more robust constraints will only be achieved with similar measurements in more objects.

In the gaseous phase, the high abundance recorded for O₂ ($\sim 4\%$) is unexpected, given its high reactivity and low interstellar abundance (Bieler et al. 2015), as is the detection of atomic

phosphorus (Altwegg et al. 2016), the origin of which could be PO also observed in the atmosphere (Rivilla et al. 2020). Nevertheless, phosphorus was also detected in the solid phase in dust particles ejected from the nucleus. There, it has been shown that it was not embedded in an oxidized form in minerals like apatite (Gardner et al. 2020).

The refractory component of the nucleus could be analyzed by mass spectrometry thanks to the study of dust particles coming from the nucleus, captured and analyzed with the COSIMA instrument. These particles are made in mass of roughly half of a nonhydrated mineral phase and half high molecular weight organic matter (Bardyn et al. 2017). This latter shows some similarities with the $\rightarrow$ insoluble organic matter (IOM) found in carbonaceous chondrites (Fray et al. 2016). The hydrogen abundance is higher in comets than in meteorites (Isnard et al. 2019) as well as D/H (Paquette et al. 2021), suggesting less processing by heat or radiations and a probable heritage in the interstellar medium.

At the surface of the nucleus, spectroimaging revealed a global coverage potentially consisting of aliphatic organics (Raponi et al. 2020) and ammonium salts (Poch et al. 2020), while the low albedo would be due to dark polyaromatics combined with opaque minerals such as FeS (Quirico et al. 2016). In addition to these remote observations of the nucleus from the spacecraft, during the very short duration of the $\rightarrow$ Philae lander odyssey at the surface of 67P, direct mass spectra measurements could be made as dust particles serendipitously entered and sublimated inside COSAC and PTOLEMY instruments at the same time automatic runs of both instruments were performed. Mass spectra could not be univocally interpreted, but they show signs of chemistry induced by UV processing of ice mixtures containing water, ammonia, methane, and carbon monoxide (Goesmann et al. 2015), while PTOLEMY results showed signs of the presence of the polymer of formaldehyde: $\rightarrow$ polyoxymethylene (Wright et al. 2015). An alternate interpretation of the Philae data has been proposed (Altwegg et al. 2017), but globally comparison between COSAC and PTOLEMY measurements with

remote sensing instruments has shown a diversity of organic molecules on the surface of 67P, which is larger than anticipated.

Future Directions

It was the first time such a broad range of instruments were integrated into a space mission. As a result, Rosetta could characterize a cometary nucleus and the evolution of its activity during its journey in the inner solar system very precisely. The mission has generated a considerable amount of data that will require years of work to be interpreted. However, as anticipated as these measurements could be, it must be recalled that comets are a heterogeneous family of objects, and extensive characterization of one of them will not be an extensive characterization of all the comets. This must be kept in mind while extrapolating to the formation of oceans and atmospheres, and if one budgets the amount of organic material delivered to Earth.

It will be extremely challenging to organize a mission as ambitious as Rosetta was. However, two projects are foreseen in the future. First, the ESA Comet Interceptor mission is planned to be launched in 2029 to be parked at a Sun-Earth Lagrange point, waiting for the arrival of a long period or even interstellar comet. Then, another step of exploration of comets would be a challenging refrigerated sample return from the nucleus.

Russian federal space agency

Definition

The Russian Space Agency was formed on February 25, 1992, succeeding the organizations involved in the development of the space activities in the Russian federation since 1989. In the early years, the role of the agency was counterbalanced by the authority of various companies, centers, and industries.

Building on past successes of the Soviet era in space, Roskosmos is now in charge of the manned space program and the development of the new rockets (Angara), as well as the improvement of existing ones (Soyuz and Proton). Since the retirement of the US space shuttles, the Russian Soyuz spacecraft are standing as the only means to send and retrieve astronauts and cosmonauts to and from the International Space Station (► ISS). The Russian Progress spacecraft remain the most regular provider of freight to the ISS.

The Russian federal space program includes also the development of satellites and missions of interest for astrobiology. For instance, Roskosmos is since 2013 a major partner of ESA for the Exomars missions, the flagship missions of the European program for the exploration of Mars.

Roskosmos shares with its military counterparts the responsibility and the costs of maintaining launch centers as Baïkonour and Plesetsk and the Y. Gagarin cosmonaut training center known as the “Star City.” The agency is also designing and building a new cosmodrome at Vostochny, in the far east of the Russian federation, to be operational in 2020.

In the next decade, in addition to Earth observation, communication, and navigation satellites, new ambitious missions to the Moon, Venus, Mars, and Europa, as well as new observatories (UV, for instance) are planned.

Rossiter-McLaughlin Effect

Nader Haghighipour

Institute for Astronomy, University of Hawaii–
Manoa, Honolulu, HI, USA

Definition

The Rossiter-McLaughlin (RM) effect is a spectroscopic effect that occurs in a stellar system with a transiting planet. In such a system, in addition to the photometric effect of the transiting planet which manifests itself as a decrease in the flux received from the star, the obscuration of the disk of the star during the transit causes changes in the disk-integrated spectrum

of the star known as the Rossiter-McLaughlin (RM) effect. As a star rotates, the portion of its disk that approaches the observer will have its spectrum Doppler shifted to shorter wavelengths (to the blue), whereas the portion that rotates away from the observer will be red shifted. When a planet transits the star, its passage in front of the star's disk disturbs the abovementioned star's rotational Doppler shift. When the planet blocks the blue-shifted part, the spectrum appears slightly red shifted. The situation is reversed when the planet covers a portion of the red-shifted segment of the stellar disk (Gaudi and Winn 2007) (Fig. 1).

Overview

The Rossiter-McLaughlin (RM) effect was described in two papers by Rossiter (1924) and McLaughlin (1924), which were published back-to-back in 1924 in the same issue of the *Astrophysical Journal*. This effect had, however, been

Rossiter-McLaughlin Effect, Fig. 4 The dependence of the RM effect on the orientation of the planet orbit relative to projection of the stellar rotation axis on the sky (Gaudi and Winn 2007)

recognized in the observations of eclipsing binary stars by Forbes (1911) and Schlesinger (1911). In connection to extrasolar planets, the Rossiter-McLaughlin (RM) effect was first observed by Queloz et al. (2000) and Bundy and Marcy (2000) during transits of HD 209458b. At present this effect has been observed in many transiting systems. Figures 2 and 3 show the RM effect for several exoplanetary systems.

Observation of the RM effect enables one to determine the trajectory of the transiting planet relative to the (sky-projected) stellar rotation axis. Specifically, one can measure the angle between the sky projections of the orbital axis and the stellar rotation axis (Fig. 4).

Rotation Planet

François Forget
Institut Pierre Simon Laplace, Laboratoire de
Météorologie Dynamique, BPParis, France

Definition

All planets rotate around their rotation axes. The rotation period is measured with reference to the distant stars. It is thus also called the sidereal period of rotation, which is different from the duration of the solar day (the time that the Sun takes to go once around the sky as seen from the planet), which is called the synodic period of rotation.

Overview

Because of the angular momentum accreted during their formation, all planets tend to rotate around their axes. The rotation rate is measured by the sidereal period of rotation, which is different from the apparent period of rotation of the Sun in the sky because, while the planet rotates, it is also moving around the Sun on its orbit (Table 1).

During its existence, the rotation of a planet may be modified by tidal effects (see Tides) resulting from gravitational forces from the Sun or a parent star or from a potential satellite. For

instance, if the Sun deforms the planet and creates a bulge in the direction of the Sun (and in the opposite direction), and if the planet rotates more rapidly on itself than its revolution around the Sun, this bulge is shifted from the subsolar point because of the nonelasticity of the planet. This induces a torque on the rotation of the planet, which tends to bring the planet’s rotation into a synchronous state with its orbital period. Such a planet would have a permanent day and night hemisphere. The synchronization time strongly increases with the orbital distance, and in the ► [Solar System](#) only planets closer to their star than the ► [Earth](#) can be affected. However, this could be the case for planets located in the ► [habitable zone](#) around low-mass stars. If the ► [orbit](#) is eccentric, the planet can instead be trapped in a spin-orbit resonance with rotation period = $(2/n) \times$ orbital period (Correia et al. 2008). This is the case for ► [Mercury](#), which rotates in exactly two-thirds of its orbital period (it rotates three times on its axis for every two orbits around the Sun).

In the case of a planet with a thick atmosphere (like ► [Venus](#)), the effect of thermal atmospheric tides must be taken into account. The Sun heats the atmosphere at the subsolar point, inducing a redistribution of the mass of the atmosphere, which also induces a torque. In the case of Venus, this effect is thought to have put Venus into the retrograde slow rotation that is observed today (Correia and Laskar 2001).

Rotation Planet, Table 1 Rotation periods for the eight planets of the solar system and Pluto. Negative periods correspond to retrograde rotation, when the planet appears

to rotate in the opposite direction than its orbital revolution around the Sun

Body	Sidereal period	Synodic period = “day”
Mercury	58.6462 Earth days	175.940 Earth days
Venus	−243.02 Earth days	−116.75 Earth days
Earth	23 h 56 min 4.1 s	24 h 0 min 0 s
Mars	24 h 37 min 22.66 s	24 h 39 min 35.24 s
Jupiter	9 h 55 min 30 s	9 h 55 min 33 s
Saturn	10 h 32 min 35 s	10 h 32 min 36 s
Uranus	−17 h 14 min 24 s	−17 h 14 min 23 s
Neptune	16 h 6.6 min	16 h 6.6 min

Rotational Axis

- [Polar Axis](#)

Rotational Speed

- [Rotational Velocity](#)

Rotational Velocity

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Synonyms

[Rotational speed](#)

Definition

The rotational velocity is the rate at which a celestial body (star, planet, galaxy) rotates on itself, generally around one of its axes of symmetry. The rotational velocity is the number of revolutions per time unit. Units are cycles s^{-1} or Hz.

The rotational velocity of a body is a result of the ► [angular momentum](#) that is possessed by the matter from which it condensed (e.g., molecular cloud, debris disk, pre-galactic halo). This quantity being conserved during any process of collapse or condensation, the object spins faster, as its size is reduced. A typical rotational velocity of a star like the Sun is one rotation per month; however, young stars can spin at a rate 40 times faster, and in the extreme case of millisecond pulsars, this rate can reach 716 rotations per second. For planets, except for those in our solar system, rotations are not generally known. Jupiter makes one rotation in about 10 h, while one rotation takes 240 days on Venus. The rotational velocity generally decreases with time through several phenomena, such as stellar winds for stars or tidal interactions for planets. In very peculiar cases, it can increase suddenly under the effect of some external forces: this is the case of millisecond pulsars, which are likely old pulsars reaccelerated by accretion of matter.

In stellar and exoplanetary studies, the rotation of the star is an important parameter since it is related to the age and ► [metallicity](#) of the star. When too large, the rotational velocity can hamper the capability to detect a planet through radial-velocity techniques. The rotation direction of a star with respect to the orbital plane of its orbiting planet(s) is now a parameter accessible in few cases, by measuring the Rossiter-McLaughlin effect in transiting planets. Comparing the direction of the axis of rotation of the star and of the normal to the planet's orbital plane gives a clue on the planet formation process: it is predicted that both directions should be roughly identical in a classical formation scheme, as the one accepted for the solar system. Indeed, all its planets but Uranus have their axis of rotation somewhat parallel to the Sun's spin

axis and perpendicular to the common orbital plane (the ecliptic plane). However, this is not a rule for exoplanetary systems: for a very significant fraction ($\sim 1/3$) of the cases where the Rossiter-McLaughlin effect could be detected, the two directions are found largely unaligned. In addition, unalignment is found predominantly in the case of stars hotter than 6,250 K.

 Earth-Life Science Institute (ELSI), Tokyo
 Institute of Technology, Meguro-ku, Tokyo, Japan
 Blue Marble Space Institute of Science,
 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Synonyms

[Optical rotatory power](#)

Definition

Rotatory power refers to a substance's ability to rotate the plane of polarization of polarized electromagnetic radiation, usually visible light. This is typically measured in solution using a polarimeter and then reported as the observed rotation $[\alpha]$:

$$[\alpha] = [\alpha]_{\lambda}^T l c \quad (1)$$

where $[\alpha]$ is the specific rotation, T is the temperature and λ are the temperature and wavelength at which the

measurement is made, l is the path length of the radiation in dm, and c is the concentration in g cm^{-3} . The product of the specific rotation atomic or molecular weight gives the rotatory power.

[\(101955\) Bennu](#)

Definition

RQ36/(101955) Bennu is a Near-Earth Asteroid (Apollo-type), of spectral type B in Tholen-taxonomy system. It was visited by the NASA/LPL's OSIRIS-REx spacecraft on a sample-return mission (101955). Bennu (formerly RQ36) is a rubble-pile asteroid with spinning-top shape. The mean diameter is 490.1 m with 498.5 m polar extent and 564.7 m $\times$ 536.1 m equatorial extent. Its sidereal rotation period is 4.296 h. Bennu is actively emitting material. The mechanism behind this activity could be stress release during thermally induced rock breakdown. Bennu's surface is dominated by highly porous boulders with low strength. This was a surprise as a smooth surface was expected from ground and space-based telescopic observations. Fine particles or dust are rare on the surface. The bulk density of Bennu is 1190 kg m^{-3} indicating a high porosity. The surface shows high abundance of hydrated minerals and similarities to CI and CM carbonaceous chondrites. It is extremely dark with a global geometric albedo of 4.4%. Bennu shows several similarities to asteroid (162173) Ryugu (JU3).

Rubisco

Juli Peretó

Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Definition

Rubisco is the acronym of D-ribulose 1,5-bisphosphate carboxylase-oxygenase. This ► [enzyme](#) catalyzes the carboxylation of ribulose 1,5-bisphosphate (RuBP) as a first step in the Calvin-Benson-Bassham cycle yielding two molecules of 3-phosphoglycerate. It is a fundamental activity for many autotrophic systems. In the presence of molecular oxygen, the enzyme oxygenates RuBP, yielding a molecule of 3-phosphoglycerate and one of phosphoglycolate (representing a loss of carbon). Rubisco is an old enzyme with a wide phylogenetic distribution among bacteria and archaea. It has been also involved in other, non-autotrophic metabolic functions like a more efficient use of carbohydrates to synthesize lipids in developing plant embryos. Its enigmatic presence also in non-autotrophic species opens the range of its metabolic functions.

Runaway Gas Accretion

Sean N. Raymond

Laboratoire d'Astrophysique de Bordeaux, CNRS, Université de Bordeaux, Bordeaux, France

Definition

Runaway gas accretion is the accelerated accretion of gas from the ► [protoplanetary disk](#) onto a

growing ► [giant planet](#). The runaway gas accretion phase is thought to occur when the mass in a planetary core's gaseous envelope is comparable to the core mass, and a large reservoir of gas remains in the disk. Runaway gas accretion is quenched when the planet carves an annular gap in the disk, having accreted all the gas within its direct gravitational influence, i.e., its ► [Hill sphere](#). Dynamical instabilities, for example, due to interactions with the gas disk, could however increase the planetary eccentricity and restore a large accretion rate of gas, for massive enough planets.

Runaway Growth

Sean N. Raymond
Laboratoire d'Astrophysique de Bordeaux, CNRS,
Université de Bordeaux, Bordeaux, France

Definition

Runaway growth is an accelerated phase in planetary growth during which the growth rate scales with the planet mass ($dM/dt \sim M^{4/3}$) such that the largest bodies get larger at a rapid and increasing rate. Runaway growth occurs in cases for which ► [gravitational focusing](#) of small bodies (planetesimals) is very strong. The runaway growth phase is thought to be quite short in most situations and to be stopped when random velocities of the planetesimals are increased to the point where gravitational focusing is stopped and accretion returns to the geometrical regime (where the collision rate is simply proportional to a body's surface area). However, in situations with very strong damping of planetesimal eccentricities (e.g., via ► [gas drag](#)), runaway growth of

► [planetary embryos](#) can be extended all the way to the point at which a growing planet becomes dynamically isolated from its neighbors by accreting all of the mass in its local neighborhood.

Ryugu Asteroid

Anny-Chantal Levasseur-Regourd
Sorbonne Université/LATMOS, Campus Pierre et
Marie Curie, Paris, France

Synonyms

[Asteroid 162173](#)

Definition

(162173) Ryugu is a near-Earth C-type (i.e., carbonaceous) asteroid. It has been, after Itokawa, the second target for an asteroidal sample return, thanks to the JAXA Hayabusa2 mission (Watanabe et al. 2019). Most interestingly, Ryugu in situ observations in 2018–2019 have confirmed, as expected from its classification, the presence of significant amounts of organic molecules, together with hydrated minerals.

Ryugu is a roundish, diamond-shaped body with an equatorial bulge. Such a shape, as previously observed during the Rosetta mission for asteroid (2867) Steins, may result from the re-accumulation of rubbles ejected by the catastrophic disruption of a larger aqueously altered parent body (Kitazako et al. 2019; Sugita et al. 2019). With a size and a mass, respectively, about 865 m and 4.5×10^{11} kg, its density is low ($\approx 1200 \text{ kg m}^{-3}$), as expected for a rubble-pile asteroid, while its rotation period is of 7.63 h. The very

dark surface of Ryugu, with a geometric albedo about 4% at 0.55 μm , suggests a high abundance in organics (Potiszil et al. 2020). Besides, observations from Hayabusa2 provide clues of space weathering and/or radiative heating of the regolith on the surface (Yokota et al. 2021; Kitazato et al. 2021). Quite a few craters have been noticed at low latitudes, together with numerous large boulders that may eventually present porosities above 70% (Sakatani et al. 2021).

Samples of Ryugu, which is estimated to contain hydrated minerals and (possibly complex polymeric) organic molecules, have been successfully collected on its surface and subsurface in 2019 (Morota et al. 2020) and have reached the Earth in December 2020 within Hayabusa2 return capsule. The mass of retrieved samples, corresponding to black granules from the surface and fragments from the subsurface, is about 5.4 g. Preliminary curatorial work on these terrestrially uncontaminated samples is mostly oriented towards organic matter, minerals, and chemistry. While Hayabusa2 mission could be extended to the exploration of other asteroids by 2026 and 2031, precise analyzes of available samples in selected worldwide laboratories should elucidate the formation of Ryugu by capture of rocky debris, the water-organics interactions, and the evolution of organic matter in the Solar System, possibly including the processing of biogenically important molecules.

S

S-Process

Nikos Prantzos
Institut d'Astrophysique de Paris, Paris, France

Definition

The s-process is one of the two main nucleosynthesis processes forming nuclei heavier than those of the iron peak. Neutron captures are slower than beta-decays (hence the s, for *slow*), keeping the flow of matter on the nuclear stability valley. The s-process occurs during helium fusion in stars, neutrons being released through $^{13}\text{C}(\alpha, n)$ or $^{22}\text{Ne}(\alpha, n)$, on timescales of 10^4 years. The latter reaction operates in the cores of massive stars and produces the light s-nuclei (with mass number $A < 90$, like Sr), while the former operates during shell He burning in ► [asymptotic giant branch \(AGB\) stars](#) and produces the heavier s-nuclei (up to ^{208}Pb).

Sagan Carl

Florence Raulin-Cerceau
Maître de Conférences, Centre Alexandre Koyré
(UMR 8560-CNRS/EHESS/MNHN/CSI)
Muséum National d'Histoire Naturelle, Brunoy, France

History

Carl Edward Sagan (November 9, 1934 – December 20, 1996) pioneered Exobiology since the beginning of planetary exploration and played a leading role in the preparation of experiments intended to detect signs of life on other planets. He was associated with the American space program since its beginning in the 1950s and contributed to the *Mariner*, *Viking*, *Voyager*, and *Galileo* missions.

His background in astronomy and astrophysics (University of Chicago) and his strong interest in the origin of life on Earth and elsewhere in the universe led him to combine scientific fields such as biology, chemistry, and astrophysics. He popularized Exobiology with talent and wrote many popular science bestsellers. Above all, he was very famous for cowriting and presenting in the 1980s the TV series *Cosmos: A Personal Voyage*, which was broadcasted all over the world.

Sagan promoted ► [SETI](#) (Search for Extraterrestrial Intelligence) thanks to his fine talent as writer (*Cosmic Connection: An Extraterrestrial Perspective*, 1973) and to the universal messages he added on the *Pioneer* and *Voyager* space probes launched in the 1970s and planned to leave the solar system. He was the author of the novel *Contact* (1985), a story dealing with SETI, which became the basis for the film “*Contact*” (1997), starring actress Jodie Foster (1962–).

His scientific career was also brilliant. He became full Professor at Cornell University in 1971, where he directed the Laboratory for Planetary Studies. He published many renowned papers about the high surface temperatures of Venus, the seasonal changes on Mars, or the reddish haze of Titan (and its *tholins*, a word that he invented). His contributions to Martian exploration (*Viking* experiments) consolidated the field of Exobiology. Editor in Chief of the International Journal *Icarus* during 12 years, he was also the cofounder and first president of the Planetary Society in 1980. He received many awards throughout his career and could be seen as a forerunner in lots of topics, thanks to his hypotheses which were confirmed many times.

Sagduction

Hervé Martin¹ and Nicholas Arndt²

¹Laboratoire Magmas et Volcans, Université Clermont Auvergne, Aubière Cedex, France

²Maison des Géosciences, LGCA, Université J. Fourier, St-Martin d'Hères, France

Definition

The concept of sagduction results from the observation that, all over the world, the Archean shields are, in the first order, affected by dome and basin vertical deformations. It consists in downward-moving diapirs (large teardrop-shaped masses of ductile material) composed of dense metavolcanic and metasedimentary rocks. This vertical tectonics is a gravity-driven mechanism (Fig. 1). The deposition of high-density lavas such as komatiites ($d = 3.3 \text{ g/cm}^3$), or even of sediments such as the banded iron formations (BIF; $d = 4.6 \text{ g/cm}^3$), onto a continental crust consisting of TTGs with a lower density ($d = 2.7 \text{ g/cm}^3$), creates a strong, inverse density gradient (Gorman et al. 1978; Barbey and Martin 1987). The return to equilibrium is achieved through komatiite sinking into TTG. Such structures are well documented in Superior Province (Lin et al. 2013), the ► [Pilbara Craton](#), Western Australia (François et al. 2014), as well as in the Dharwar craton in South India (Choukroune et al. 1997; Chardon et al. 1998).

Komatiites are abundant in Archean terranes. Indeed, after 2.5 Ga, Earth's internal temperature became too low, and consequently, basalts were generated instead of komatiites. However, basalt density does not exceed 2.8 or 3 g/cm^3 , which is too low for generating an inverse density gradient, sufficient for sagduction to be initiated. Therefore, as komatiites are necessary to trigger sagduction and that they were no longer generated after 2.5 Ga, sagduction and vertical tectonics also logically ended and disappeared after 2.5 Ga.

Sagduction, Fig. 1 The three main steps of sagduction: (1) In a greenstone belt, high-density komatiites ($d = 3.3 \text{ g/cm}^3$) emplace over lower density ($d = 2.7 \text{ g/cm}^3$) TTG basement rocks, thus generating an inverse density gradient; (2) komatiites sink downward into the TTG basement which favors a relative upward motion of the TTG; and

(3) the movement is amplified creating a sedimentation basin at the center of the greenstone belt. *Green* is komatiites, *pale yellow* is TTG basement, and *yellow gold* are sediments possibly including Banded Iron Formations

If some authors consider that this tectonic style is entirely compatible with plate tectonics, others believe that plate tectonics could not have operated on a hot early Earth.

Eoarchean · Earth's first crust · TTG · Early differentiation · Magma ocean · Traces of life

Acronyms (Optional)

SHC

Definition

The Saglek-Hebron Complex (SHC) is an Eoarchean granite-greenstone terrane, hosting some of the oldest rocks on Earth, and where some of the earliest traces of life might have been recorded. The SHC is located in northern Labrador (Canada) and is part of the North Atlantic Craton, known as the Nain geological province. The lithologies found in the complex include mafic metavolcanic rocks, ultramafic rocks, and chemical metasedimentary rocks, occurring as large enclaves of up to several hundreds of meters, hosted in Neoproterozoic to Eoarchean felsic gneissic rocks. The SHC rocks are often correlated with those from the Eoarchean ► [Isua supracrustal belt](#) of southern West Greenland.

History (Optional)

Research in northern Labrador started in the late 1960s based on geophysical studies of the Canadian and Greenland cratons associated with the discovery of ≥ 3700 Ma ► [Amîtsoq gneisses](#) on the western coast of Greenland (Black et al. 1971). The Amîtsoq gneisses contain supracrustal enclaves (such as the Isua supracrustal belt), which are comparable to those found in the

Uivak gneisses of the Saglek-Hebron Complex in northern Labrador. Given the lithological similarities and comparable emplacement ages, it was suggested that the Amîtsoq and Uivak gneisses and their supracrustal rocks shared a common geological history (e.g., Bridgwater and Schiøtte 1991). As the oldest terrestrial crust so far discovered, it attracted considerable interest for research between the 1970s and 1990s. The first radiometric dating studies from Hurst et al. (1975) and Barton (1975) revealed an age of 3600 Ma for the Uivak gneisses. Subsequent studies focused on the petrology and geochemistry (e.g., Bridgwater and Collerson 1976), to identify the main lithostratigraphic units in the SHC, as well as using U-Pb geochronology on zircons to refine the chronology of deposition of these units (e.g., Collerson 1983). With the development of new methods of investigation and recent progress in Hadean and Archean geology studies, there has been a renewed interest in research on the SHC since 2015, whose discoveries are summarized below.

Overview

The Saglek-Hebron Complex is an ancient terrane of metamorphosed granitoids and supracrustal rocks located in northern Labrador (Canada) and is part of the North Atlantic Craton. This terrane is one of the handful places on Earth where rocks from the Eoarchean Era (4.0-3.6 billion years) are preserved. The study of these rocks, therefore, provides valuable information regarding the geological processes responsible for the formation of Earth's most ancient crust. The oldest granitoids in the SHC have been dated by U-Pb geochronology on zircons at ~ 3.9 Ga (Collerson 1983; Regelous and Collerson 1996; Shimojo et al. 2016; Komiya et al. 2017; Vezinet et al. 2018; Wasilewski et al. 2021). Younger granitoids are also present in the SHC, with ages spanning from ~ 2700 Ma to ~ 3900 Ma, formed during at least six distinct magmatic events (e.g., Wasilewski et al. 2021) and metamorphosed at ~ 3600 Ma and up to granulite facies at ~ 2700 Ma (Kusiak et al. 2018; Sałacińska et al. 2019). The Nd isotope

composition of those granitoids, along with Hf isotope compositions of their zircons, allows tracking the evolution of the crust through time and comparing this evolution with other ancient terranes. These studies show the granitoids were produced by the remelting of Mg-Fe-rich crust, possibly ► [Hadean](#) in age, as well as the reworking of the Eoarchean felsic crust throughout the Archean (Wasilewski et al. 2021). After the Paleoarchean, the zircon Hf isotope compositions suggest the input of more juvenile material (Wasilewski et al. 2021). This shift in source material has also been observed in other ancient crust outcrops (e.g., Acasta gneisses, Amitsoq gneisses) suggesting a planetary-scale transition for crustal formation processes. Slightly elevated $d^{18}O$ values (up to +6.6%) in zircons from Eoarchean granitoids support interaction of their protolith with hydrosphere at relatively low temperature (150–200°C) (Vezinet et al. 2018).

The SHC supracrustal rocks are mostly metamorphosed basalts locally interbedded with detrital and chemical sediments. ► [Pillow lava](#) structures can be observed, similar to those found in the Isua supracrustal belt (Greenland) and in the Nuvvuagittuq greenstone belt (Canada), evidencing for submarine magmatism on Earth's surface in the Eoarchean. The major and trace element compositions of the metabasalts are similar to those of modern tholeiites (Wasilewski et al. 2019). As opposed to the boninite-like basalts (boninite is a mafic extrusive rock high in both Mg and Si formed in subduction arc environments) found in Greenland (e.g., Polat et al. 2002), metavolcanic rocks from the SHC do not exhibit geochemical evidence of possible subduction-zone settings (Wasilewski et al. 2019). Therefore, while the geochemical composition of the basalts from Greenland suggests plate tectonics had already started in the Eoarchean, similar arguments cannot be made in the SHC. The SHC also includes ► [ultramafic rocks](#), which origin and age have been debated. Collerson et al. (1991) proposed that some of these rocks were similar to ► [komatiites](#), which derive from high-degree partial melts, seen exclusively in the Archean. They also proposed that some ultramafic rocks were 4-billion-year-old

slices of lithospheric mantle, making these the oldest fragments of mantle preserved on Earth. More recent studies, however, have obtained younger 3800–3600 Ma ages from these rocks (Ishikawa et al. 2017; Morino et al. 2017, 2018). Using the major and trace element compositions, Wasilewski et al. (2019) proposed that rather than mantle fragments, these ultramafic rocks were ultramafic cumulates crystallized from komatiitic or picritic basalts. Both, the metabasalts and ultramafic rocks were studied using the short-lived ^{146}Sm - ^{142}Nd system (half-life of 103 Ma), and ^{142}Nd variations found in these rocks suggest that their mantle source differentiated ~4.4 billion years ago (Morino et al. 2017).

Tashiro et al. (2017) studied ~3.95 Ga metasedimentary rocks from the SHC and found large fractionations between $\delta^{13}C$ in carbonates and in graphite (up to 25 per mil), which they interpret as evidence of biological activity in the Eoarchean. The age assumed for these metasedimentary rocks and associated traces of life has however been questioned, since it relies on field relationships and the geochronology of surrounding granitoids (Whitehouse et al. 2019). The use of $\delta^{13}C$ as isotopic biosignatures has also been challenged since abiotic processes, and contamination might mimic the same signatures (Javaux 2019). Nevertheless, evidence of isotopically light $\delta^{13}C$ compositions interpreted as biogenic tracers have also been proposed in other ancient terrains such as the Eoarchean Isua supracrustal belt (Ohtomo et al. 2014), as well as potential fossil evidence in the Hadean ► [Nuvvuagittuq greenstone belt](#) (Dodd et al. 2017). Since pillow lavas in all these terrains imply the presence of liquid water on Earth's surface, life could very well have been developed in the first few hundred million years after Earth's birth.

restricted Earth return mission. Such samples might contain extraterrestrial materials that, if released, could cause harm to the environment of the Earth and need to be contained. Further, the samples need to be protected from contamination by terrestrial organisms and biomolecules, so that life detection experiments performed on these samples do not detect terrestrial biology by mistake.

The sample receiving facility is the location in which returned sample canisters can be safely opened, and samples identified, sorted, tested, and curated.

The sample safety assessment protocol is performed on samples to determine whether it is safe to release materials (with or without a subsequent sterilization step) to scientists studying the samples in laboratories without containment facilities and practices in place.

Sample Safety Assessment Protocol

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

Any spacecraft mission bringing samples to Earth from another planetary body is subjected to an assessment for ► [planetary protection](#) according to the recommendations of the ► [COSPAR](#) planetary protection policy. If the planetary body has (either now or in the past) had the potential to host indigenous life, then the return mission is

categorized as “restricted Earth return.” This means that any returned samples must be subjected to rigorous analysis in order to assess the risk of releasing any possible extraterrestrial life into the Earth’s environment. A sample safety assessment protocol that has been reviewed and concurred by an appropriate nonadvocate group of scientific experts is performed to determine whether extraterrestrial organisms or other hazards are present in materials returned from other planetary bodies, before the sample is confirmed as safe to release to other laboratories or whether the sample must remain contained in the ► [Sample Receiving Facility](#).

History

This Protocol was previously known as the Bio-hazard Assessment Protocol.

Sanukitoid

Hervé Martin
Laboratoire Magmas et Volcans, Université
Clermont Auvergne, Aubière Cedex, France

Keywords

Archean-Proterozoic transition · Continental crust · Mantle metasomatism

Synonyms

[High-magnesium granodiorite](#)

Definition

Sanukitoids are intermediate to felsic igneous rocks, which possess both modern crust characteristics (i.e., richness in K) and Archean TTG features (i.e., fractionated rare-earth element patterns). Most of them were generated between 2.7 and 2.3 Ga on Earth.

Overview

Sanukitoids, also called *high-magnesium granodiorites*, were first described by Shirey and Hanson (1984). They consist in a complete magmatic series, from diorite to granite, the most common facies consisting in monzodiorites and monzogranites. Typically, they are rich in both K-feldspar phenocrysts and mafic minerals such as biotite and hornblende with sometimes subordinate amounts of clinopyroxene.

Sanukitoids can occur as plutons of all sizes, with a broad range of crustal emplacement levels and degrees of heterogeneity. In the Central Pilbara Craton, Western Australia (Smithies and Champion 1999), sanukitoids form small (<1 km), homogeneous stocks of shallow-emplaced magmas; while in South India (Closepet Granite; Moyen et al. 2001), they form a huge intrusive body that is about 400 km long and 20 km wide and is rooted in the lower granulitic crust.

From the chemical point of view, these rocks possess both modern characteristics (i.e., richness in K) and Archean TTG features (i.e., fractionated rare-earth element patterns). In other words, their composition is intermediate between that of Archean TTG and that of the modern continental crust.

Melting experiments and petrogenetic geochemical modeling (Rapp et al. 2010) show that sanukitoids may have formed by either (1) melting of mantle peridotite previously transformed (metasomatized) by felsic melts having a TTG composition or (2) by reaction between TTG melts and mantle peridotite (assimilation; Martin et al. 2009).

The transitional character of sanukitoids is not only compositional but also chronologic, since most of them were emplaced between 2.7 and 2.3 Ga, at the Archean-Proterozoic boundary, the period when the Earth geodynamics changed from archaic to modern style (Martin et al. 2009; Heilimo et al. 2010; Laurent et al. 2011). Indeed then, the source of juvenile continental crust changed from basalt melting, producing TTG to fusion of peridotites, resulting in calc-alkaline magmas; the tectonic regime changed from horizontal + vertical in the Archean to only horizontal in Paleoproterozoic. All these fundamental evolutions, as well as the disappearance of komatiites after 2.5 Ga, result in the progressive cooling of our planet.

Sarcosine

Kensei Kobayashi

Yokohama National University, Yokohama, Japan

Synonyms

[2-\(Methylamino\) acetic acid](#); [N-Methylglycine](#)

Definition

Sarcosine is a ► [nonprotein amino acid](#) and a structural isomer of alanine. While alanine is chiral, sarcosine is achiral since it does not have an asymmetric carbon atom. Its molecular structure is $\text{CH}_3\text{NHCH}_2\text{COOH}$, and its molecular weight is 89.093. Though sarcosine is not a protein ► [amino acid](#), it is a biogenic amino acid and is widely distributed in organisms. It is widely distributed in foods such as egg yolks, meats, and vegetables. Since it has no amino group ($-\text{NH}_2$) but an imino group ($-\text{NH}-$), it requires special care in amino acid analysis, since sensitive amino acid detection often requires derivatization of the amino group. It is one of the most abundant amino acids in prebiotic chemistry. Sarcosine was found in Miller’s spark discharge products and also in extracts from carbonaceous chondrites such as the Murchison meteorite.

Giant planets

Definition

Saturn by order of mass, size, and heliocentric distance is, after Jupiter, the second among the solar system's giant planets. Its mean distance to the Sun is 9.5 AU. Its diameter is 120,530 km or 9.45 times the Earth's diameter and its mass amounts to 95 terrestrial masses. Its density is 0.69 g/cm^3 such that Saturn is the lightest solar system planet. Saturn is best known for its extensive ring system, much larger and more massive than the ones of the other giant planets. Its atmosphere shows a strong dynamical activity and its magnetosphere, perturbed by the ring system, is unique in the solar system.

Overview

Saturn as a Giant Planet

Jupiter and Saturn have the same basic chemical composition, dominated by protosolar gas (mostly hydrogen and helium) which accreted on their rock/ice core at the time of their formation; they are called the gas giants. The difference in density between Jupiter (1.3 g/cm^3) and Saturn can be explained by Jupiter being more than three times more massive than Saturn, thus causing a much stronger compression. Basically, Jupiter and Saturn have the same chemical composition, dominated by the protosolar gas (mostly hydrogen and helium) which collapsed on their rock/ice cores at the time of their formation. Because of hydrogen and helium gas dominating their

composition, they are called the gas giants. In contrast, the two other giant planets, Uranus and Neptune, accreted a minor fraction of protosolar gas around their cores. Their compositions are dominated by water, methane and ammonia, chemical components collectively called planetary ices, and are thus called the ice giants.

Early Exploration

As for Jupiter, the astronomical observation of Saturn started at the beginning of the seventeenth century, when Galileo Galilei turned his first refractor towards the Moon, planets, and stars. Galileo soon noticed that Saturn's shape was slowly evolving, due to the changing orientation of its rings with respect to the Earth, but he was not able to explain this phenomenon. The answer was provided by Christiaan Huygens in 1659 who proposed that a flat equatorial ring was surrounding the planet. In 1675, Giovanni Domenico Cassini discovered the Cassini division in the ring system and, one century later, in 1787, Pierre-Simon de Laplace, on the basis of dynamical studies, concluded that Saturn was surrounded by a large number of narrow rings.

In 1676, Cassini discovered the equatorial belt of Saturn. In 1787, William Herschel measured the flattening of the planet and, 3 years later, the planet's rotational period, which at 10.6 h, shows that Saturn, as Jupiter, is a fast-rotating object. The average angular diameter of Saturn is 16 arcsecs.

Space Exploration

Space exploration of Saturn started with the Pioneer 11 encounter. Launched in 1973 by NASA, Pioneer 11 used a gravity-assist flyby of Jupiter to encounter Saturn in 1979. In addition to a camera, UV and IR photometers, its instruments were specifically designed for the study of both the planet and of the interplanetary magnetic field. Pioneer 11 sent back amazing images of Saturn's rings, discovered two new satellites and a new ring, and explored Saturn's magnetosphere.

Only 1 year after Pioneer's discoveries, the Voyager 1 spacecraft flew by Saturn and brought even more spectacular results. The Voyager

mission, composed of two identical spacecraft, was designed to explore the four giant planets by successive flybys during 1979 and 1989. Saturn was approached in 1980 by Voyager 1 which also flew close to Titan and in 1981 by Voyager 2 which then continued its way to Uranus and Neptune. Voyager 1 measured the atmospheric composition of Saturn, tracked its atmospheric spots, measured its zonal winds, and detected a high-level auroral activity.

Since the Voyager era, Saturn was continuously monitored by ground-based telescopes and by the Hubble Space Observatory. The next milestone was the ambitious Cassini-Huygens mission (see entry), jointly built by NASA and ESA, and devoted to the exploration of the Saturnian system. Launched in 1997, the Cassini orbiter approached Saturn in 2004. On January 14, 2005, the Huygens probe successfully landed on Titan, sending the first images of the satellite's surface. Since 1995, the Cassini orbiter has been exploring Saturn, its rings and satellites, bringing an impressive number of results and discoveries, including the rings' fine structure, cryovolcanism on Enceladus and lakes on Titan. The mission ended on September 15, 2017, with a plunge into Saturn's atmosphere, after having completed observations over almost two seasons of a Saturnian year (Fig. 1).

Dynamical Structure

Alike Jupiter, Saturn's disk shows a zone and belt structure, ascribed to a convective, Hadley-type circulation of a fast-rotating body. The zones are associated to ascending cloudy regions, while the belts are dry regions of subsidence. The cloud structures on Saturn appear less featured than that of Jupiter. The more uniform yellowish colour of Saturn is explained by thicker ammonia clouds resulting from the lower surface temperature of this planet. In spite of this apparent uniformity, Saturn exhibits a strong dynamical activity. At the South Pole, Cassini visible and near-infrared images have revealed the presence of a hurricane with a giant eye, sharing some similarities with terrestrial hurricanes but of a much larger size. In contrast, the northern hemisphere displays

Saturn, Fig. 1 Saturn and its ring system, as observed by the Cassini orbiter. (© NASA)

a hexagonal feature, already observed on the Voyager images that encircle the North Pole at a latitude of 77° N. It is similar to the Earth's polar vortex, except that it possesses six branches instead of being circular. This feature is the signature of a long-lived, complex system of convective cells which extend deep into the planet's troposphere. The mechanism which drives these huge cyclonic features is still not understood.

In December 2010, a huge storm appeared in Saturn's Northern hemisphere at a latitude of 32° N. It rapidly extended over all longitudes to form a large band of white clouds, monitored by the Cassini spacecraft. Five such phenomena have been observed in the past 150 years with a mean period of a Saturnian year (subject to significant fluctuations) and seem to occur during summer solstice when insolation is at its maximum, alternating between equatorial and northern mid-latitudes. The Cassini instruments recorded tropospheric cooling at the location of the storm eruption, suggesting a massive upwelling, and strong stratospheric heating (up to 80 K above quiescent conditions at 2 mbar), probably caused by planetary wave propagation from the tropospheric storm.

Atmospheric Composition and Structure

The thermal structure of Saturn is very similar to the Jovian one, with a troposphere, a tropopause, and a stratosphere. The tropopause is located at a pressure level of 100 mbar, as in the case of the other giant planets. Because of its large heliocentric distance, its temperature (80 K) is lower than at the Jovian tropopause (110 K). Below the tropopause, as in the case of Jupiter, the troposphere

extends downward with an adiabatic gradient. Above the tropopause, in the stratosphere, temperature increases with altitude. The heating takes place at higher altitudes than on Jupiter, which implies different heating mechanisms.

The cloud structure of Saturn is also similar to the Jovian one, but it appears at higher pressure levels due to the colder environment. Thermochemical models predict a NH_3 cloud at about 1.5 bar, a NH_4SH cloud at 4 bars, and an H_2O cloud at about 10 bars. Only, the thick ammonia cloud deck is observed; the other clouds are too deep to be observable. In the stratosphere, a haze is observed, probably due to hydrocarbon condensates.

Similar to Jupiter's, Saturn's atmosphere is dominated by hydrogen (84%) and helium (16%). At the time of the Voyager encounter (1980), a very low helium abundance was inferred from infrared and radio-occultation data. This result was interpreted in terms of helium condensation inside a liquid hydrogen ocean in the interior of the planet: sinking of helium droplets (helium rain), falling toward the centre would lead to the depletion of the helium gas in the outer atmosphere; in addition, it would release some internal energy, as also observed by Voyager (see below section "[Internal Structure](#)"). However, in 2000, Voyager data were reanalysed, which resulted in a higher helium abundance and in better agreement with the Jupiter value. In both cases, the helium abundance is lower than the protosolar value, so that helium condensation within the interior of the planets might be responsible for this depletion, and also accounting partly for the internal energy source required to balance the observed luminosity of the planet.

As a result, the planet's strong dynamical activity, the tropospheric abundance of PH_3 in Saturn is higher than in Jupiter; indeed, PH_3 is a disequilibrium species which is not expected to be observable according to thermochemical equilibrium models. Its presence in the planets' spectra is believed to be the signature of convective motions, particularly strong in the case of Saturn. As in Jupiter, many hydrocarbons are found in Saturn's stratosphere, resulting from methane photodissociation. Oxygen species (H_2O , CO_2) have also been detected by the Infrared Space Observatory (ISO), as in the other giant planets and Titan, and water has been recently monitored with Herschel. The oxygen species are believed to come from an external source, either local (Saturn's rings and satellites) or interplanetary (comets). Enceladus, with its H_2O geysers, is probably the dominant source of oxygen on Saturn.

As Saturn has not yet been explored by an entry probe, we have little information about the abundances of heavy elements. Still, a C/H ratio = 9 can be inferred from the CH_4 abundance; which is consistent with the value expected from a model assuming that giant planets formed from a rock/ice core of about 10–15 terrestrial masses.

Internal Structure

Saturn's interior can be probed indirectly from the measurements of its basic parameters (mass, radius, density) and its gravitational moments. Additional information is deduced from its composition and its luminosity. The Voyager IRIS infrared spectrometer measured the planet's emission over the total infrared range and led to the conclusion that the internal energy of Saturn is 1.78 times the absorbed solar energy, i.e., slightly greater than in the case of Jupiter.

The structure of Saturn, as predicted by theoretical models, is similar to Jupiter's, with a central core of ices and rocks, surrounded by an ocean of metallic hydrogen and a layer of molecular hydrogen, mixed with helium. The central pressure could be about 9 mbar (0.9 TPa) with a central temperature of $\sim 10,000$ K. As mentioned above, the origin of Saturn's internal energy could

partly result from the condensation of helium in addition to cooling upon contraction of the planet which slowly releases gravitational energy accumulated during its accretion phase.

The Magnetosphere of Saturn

Saturn's magnetosphere was unknown prior to the flybys of Pioneer 11 in 1979 and of Voyager 1 and 2 in 1980 and 1981. Since 1995 until 2017, Saturn's environment has been monitored in depth by the Cassini orbiter.

Saturn's magnetic field is almost aligned with the planet's rotation axis. As in the case of Jupiter, the fast rotation of the planet induces a corotation of the plasma and the same general magnetospheric structure. However, Saturn's magnetosphere is coupled to specific sources: Titan, as a provider of H^+ and N^+ ions, the neutral torus of hydrogen and nitrogen, the icy satellites, the rings, and the ionosphere.

Auroral phenomena appear at fixed locations at high northern and southern latitudes. In the radio range, Voyager discovered the Saturn Kilometric Radiation (SKR), auroral and nonthermal radiation, similar to the Auroral Kilometric radiation (AKR) on Earth.

Measuring the radio emission of giant planets is important for determining precisely the rotation period of the planet's interior. From Voyager measurements, Saturn's rotation period was found to be 10 h 39 min 22.4 s. However, subsequent measurements by the Ulysses probe and more recently by Cassini have suggested a rotation period apparently larger by more than 6 min. Recently, it was shown that the rotation period is actually modulated by the solar wind: the dynamical pressure of the solar wind induces changes in the speed of the solar wind as it interacts with Saturn's magnetic field, and thus induces a slight change in the measured radio emission. More recent values of the rotation period are between 32 min 35 s and 10 h 33 min 13 s.

Scale Height

Lisa Kaltenegger
Cornell University, Ithaca, NY, USA

Definition

A scale height H is the distance over which a quantity decreases by a factor of e (the base of natural logarithms). For planetary atmospheres, it is the vertical distance upwards over which the pressure of the atmosphere decreases by a factor of $1/e$. For an isothermal atmosphere,

$$H = kT/\mu g$$

where k is the Boltzmann constant ($1.38 \times 10^{-23} \text{ J K}^{-1}$), T the mean planetary temperature in Kelvin, μ the mean molecular weight of the planetary atmosphere (kg), and g the

acceleration due to gravity (ms^{-2}). H in a planetary atmosphere is highest for high temperatures and small μ . Assuming absorption features in an atmosphere are proportional to the scale height, they are largest for hot atmospheres with low mean molecular weight (e.g., made out of hydrogen and helium); they have already been detected in transmission spectroscopy for hot extrasolar giant planets.

Scale-Free Networks

Tom Lenaerts
Département d'Informatique, Université Libre de Bruxelles, Brussels, Belgium

Keywords

Complex network · Power law · Scale free · Small world

Synonyms

[Power-law networks](#)

Definition

Networks or graphs are called scale free when their degree distribution, i.e., the distribution of the number of nodes that have a particular degree, decays like a power law (Dorogotsev and Mendes

2003). Researchers have observed that a lot of real-world networks like the Internet or social interaction networks have a topology that comes close to this kind of network.

Overview

The relevance of scale-free networks to represent real-world networks was underlined by the work of Barabási and Albert in 1999 (Barabási and Albert 1999), in which they examined the structure of a number of large networks like the Internet and the coauthorship network between scientists. They showed that these networks follow a power-law distribution, meaning that $P(k)$, which is the probability that a particular vertex in the networks has k interactions, decays as $P(k) \sim k^{-\gamma}$. For instance, the value for γ for the Internet is approximately 2.1 and $\gamma \approx 3$ for the coauthorship network. In addition, they explained the origin of these networks through a simple growth mechanism called the preferential attachment rule. This rule specifies that networks grow by adding new vertices and that these vertices connect not with randomly selected vertices but with popular vertices, meaning here the vertices that already have a high degree. Artificially growing a network in this way produces a network with a power-law degree distribution. This observation was crucial, since prior to their work people mostly assumed that most real-world networks were simply random (small-world) networks (Watts and Strogatz 1998), where the degree distribution corresponds to a Poisson distribution. In the early years after this seminal work, scale-free topologies were discovered in a wide variety of domains, ranging from signaling and metabolic networks to food webs, over different social networks. Yet, it was also observed that a wider variety of heterogeneous topologies exist (Amaral et al. 2000). For instance, Stanley and colleagues observed that the tail of the degree distribution of a movie-actor network decays faster than a power-law network (broad-scale) and that the neuronal network of the worm *Caenorhabditis elegans* decays even faster than a network (single scale). To explain the growth of

the other classes of networks, they extended the growth mechanism with a vertex-dependent aging (or cost) factor. This factor takes into account that there is a limit to how long a vertex can keep receiving new links, which is obviously the case in the movie-actor network. Thus when aging is slow (fast), the scale-free network will turn into a broad-scale (single-scale) network. The research on scale-free networks was immensely popularized by the book *Linked: The New Science of Networks* (Barabási 2002).

Scattering

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Definition

Scattering is a process in which a photon, or a particle, interacts with an atom, molecule, or

particle and emerges in a different direction without, or with only a slight, difference in energy. In the interstellar medium, radiative scattering plus absorption by dust grains (in which the photon's energy is converted into heat and possibly lower energy radiation) combine to produce extinction. In planetary atmospheres, scattering by molecules and cloud particles plays an important role in the diffuse reflection and transmission of radiation.

Secular Dynamics

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

Secular dynamics refers to the gravitational interactions and subsequent evolution of orbits among multiple bodies around a central mass. The semi-major axes of secularly interacting bodies remain constant, but other orbital parameters such as eccentricities, longitudes of pericenter, inclinations, and longitudes of ascending node oscillate with time. For low eccentricities and inclinations, motion in the plane is decoupled from motion out of the plane (see also ▶ [“Kozai Mechanism”](#)), that is, the eccentricities and inclinations will oscillate on different timescales, called the secular periods.

Cross-References

- ▶ [Kozai Mechanism](#)

Secular Resonance

Rory Barnes

Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

In planetary dynamics, secular resonance is the commensurability of two or more apsidal or nodal precessional frequencies. When multiple planets (more than two) are in a system, their mutual gravitational perturbations cause the shapes and relative orientations of their orbits to change with time (see ► [“Secular Dynamics”](#)). In some cases, the ratios of the frequencies can be close to the ratio of small integers (a commensurability). In these cases, repetitive forces can drive larger or faster oscillations than if the commensurability was not present. This term should not be confused with apsidal libration, which only means the lines of apse are librating.

Sedimentary Rock

Daniele L. Pinti

GEOTOP Research Center for the dynamics of
the Earth system, Université du Québec à
Montréal, Montréal, QC, Canada

Definition

A sedimentary rock is a lithified deposit of detrital particles such as gravel, sand, silt, or ► [clay](#); of

(bio)-chemical precipitates (including ► [evaporites](#)) and of organic material. Sedimentary rocks are produced at the surface of the Earth or of a planetary body through processes of mechanical erosion or fragmentation (forming terrestrial regolith and planetary regolith), chemical alteration (both processes reunified under the term “► [weathering](#)”), dissolution, and precipitation. Loose products of those processes are designated as “sediments.” Lithification of sediments through ► [diagenesis](#) brings them to become a lithified sedimentary rock. Sedimentary rocks are usually deposited in sedimentary basins, where the volume of sediments or sedimentary rocks depends on two main parameters: the rate of sedimentation and the space of “accommodation,” the latter increasing through gravity and/or tectonic subsidence. For their nature and mode of formation sedimentary rocks are a record of the past tectonic, climatic, and biological history of the region. The sedimentary record of the Ancient Earth is thus important to investigate, because the lithological, biological, or structural nature of the few sedimentary rocks preserved in Archean terranes can give information on the surface environments where potentially life developed.

Overview

Differently from ► [igneous rocks](#) that form from molten material of the mantle or refusion of the continental crust at depth (*anatexis*) and ► [metamorphic rocks](#) which form at depth under high temperatures or pressures (or both), sedimentary rocks form at the surface of the Earth. Thus, their lithological nature, texture, and fabric reflect or are conditioned by the environmental conditions at the surface of the Earth. Only during the process of lithification (diagenesis), sediments can eventually be buried at temperatures not exceeding 200° C and depths of 10,000 meters. These are the P,T conditions at the boundary between the sedimentary and the metamorphic formational environments.

Sedimentary rocks are classically grouped in three types: clastic or detrital; chemical; and

organic. Clastic rocks are composed of debris of preexisting rocks of any nature, igneous, metamorphic, or even sedimentary. Debris is produced by mechanical erosion and/or chemical weathering, with water interacting with the mineral structure of the rock through mainly ► [hydrolysis](#) (any chemical reaction in which a molecule of water breaks one or more chemical bonds). The first process produces clastic deposits called terrestrial *regolith* (on the Moon, regolith are clastic rocks formed during asteroid impacts). The second, derived from chemical weathering, is named *alterite*. Hydrolysis reaction with silicates can bring to the incorporation of hydroxyls (OH-) in the structure and the transformation into secondary minerals called commonly clay minerals. The silicate structure can be completely dismantled by hydrolysis and residual ions form hydroxides (such as Gibbsite or $\text{Al}(\text{OH})_3$) which are found in extreme weathered soils called *laterites*. Soils are the ultimate transformation of a rock by chemical (and biological) weathering: carbonate rocks can form *calcrete*, while silicate rocks can form a variety of soils; the most weathered being indeed *laterite*. Common clastic sedimentary rocks are conglomerate, sandstone, siltstone, and pelite (or mudstone).

Chemical sedimentary rocks are dominated by evaporites, which precipitate by strong evaporation of seawater along coastal plains (*sabhka*) or closed lakes in arid regions (*playas*). Main evaporitic minerals composing this class of rocks are calcite (CaCO_3), halite (NaCl), gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), and sylvite (KCl), although many other evaporitic minerals are known. However, being composed of water-soluble minerals, evaporitic rocks are badly preserved in the geological record, and they are mainly found on Earth in sedimentary sequences deposited in the last 500 Ma. ► [Archean evaporites](#) are rare and mainly transformed by later reprecipitation or replacement, as silicified selenite (a variety of gypsum) possibly found in Strelley Pool Chert, Pilbara craton, Western Australia (Lowe 1983).

Carbonates (and perhaps ► [banded-iron formation](#); e.g., Hashizume et al. 2016) are almost always biologically mediated. Since the late

Ediacaran, specialized cells in metazoans precipitate calcite and aragonite from ambient water, forming calcareous endo- or exoskeletons in the shape of shells, tests, spicules, and many other forms. In ► [stromatolites](#) and other microbialites (carbonate bio-construction), photosynthetic activity increases the alkalinity in the near-cell environment, triggering the nucleation and precipitation of aragonite or calcite. Other biological sediments are those deposited in anoxic environments, such as basins with restricted circulation, barred coastal lagoons, or deltaic swamps where organic matter of marine or continental (plants) origin is preserved by complete oxidation.

Most sedimentary rocks are characterized by a large inventory of sedimentary structures, including a variety of bedforms from deposition by highly variable agents under varying conditions. Among them, sedimentary structures controlled by the deposition of sedimentary grains under marine or lacustrine currents, such as *ripple marks* or *cross-bedding*, are important because they give information on paleoceanic currents or, as in case of Archean of the presence of liquid water at the surface of the planet.

Sedimentary rocks are not a prerogative of the planet Earth. Martian exploration has shown numerous evidences of sedimentary rocks on the surface of Mars (e.g., Grotzinger et al. 2011). The presence of numerous sediments deposited clearly in water bodies such as marine and fluvial clastic and evaporitic deposits or mega-floods (e.g., Baker 2009) suggested more clement climatic conditions in the far past of the planet, likely in pre-Noachian, when a magnetosphere protected Mars and allowed liquid water to exist at a global scale.

Selection

Susanna Manrubia

Systems Biology Program, Centro Nacional de Biotecnología (CSIC), Madrid, Spain

Definition

In biology, selection refers to the preferential survival and reproduction of organisms in response to particular phenotypic traits. Limited environmental resources and a growth of populations above its capacity promote competition among organisms and lead to ► [natural selection](#). Natural selection acts at many different levels, from genes and genomic elements to populations. Darwin introduced sexual selection as a preference of females for attractive males: colorful bodies, long feathers, or big horns are instinctually evaluated as a measure of their competence to breed

healthy progeny. Humans perform artificial selection to improve desired qualities in a plant or animal. In vitro evolution is a particular form of artificial selection focused on molecular phenotypes. Though selection acts on the ► [phenotype](#), only heritable traits (coded in the ► [genotype](#)) can be selected.

[\\$13-Selanyl-2-aminopropanoic acid](#)

Definition

Selenocysteine is a rare biological ► [amino acid](#) found in several enzymes. Its structure is similar to cysteine, but it has a selenium atom replacing the usual sulfur atom, thus forming a selenol group. Selenocysteine is a stronger acid and has a higher reduction potential than ► [cysteine](#). These properties make it optimal for incorporation in proteins involved in antioxidant activity.

Selenocysteine is not directly coded for in the genetic code; rather, it is encoded by a UGA ► [codon](#), which is normally a stop codon. The UGA codon is made to encode selenocysteine by the presence of a SECIS (SElenoCysteine Insertion Sequence) element in the coding mRNA. The SECIS element is defined by characteristic nucleotide sequences and secondary structure base-pairing patterns. In bacteria, the SECIS element is located immediately following the UGA codon in the reading frame for the selenoprotein. In archaea and eukaryotes, the SECIS element is in the 3' untranslated region of the mRNA and can direct multiple UGA codons to encode selenocysteine residues. Unlike the other coded amino acids, no free pool of selenocysteine exists in the cell. Its high reactivity would incur damage to cells. Instead, cells store selenium in the form of the less reactive selenide (H₂Se). Selenocysteine is biosynthesized in situ on a specialized tRNA. In these days, selenocysteine is sometimes included in additional protein amino acids together with pyrrolysine.

Synonyms

[Self-organization](#)

Definition

Self-assembly is the process by which pre-existing components (separate or distinct parts

of a disordered structure) autonomously organize into patterns or structures without external intervention.

Overview

Self-assembly processes are responsible for the generation of much of the order in nature (Philp and Stoddart 1996; Whitesides and Grzybowski 2002). They involve components at different scales, such as molecules, cells, and organisms. The characteristics of the components control how they interact with each other and thus the patterns and structures that emerge. The components must be mobile, being either externally propelled or self-propelled. In many self-assembling systems, the components selectively bind to, or selectively disband from, each other. Such selective binding regulates, for instance, the replication of genetic information in the assembly of the DNA double helix.

Self-assembly processes may be either static or dynamic. In static self-assembly, the systems of components do not dissipate energy and reach an ordered state at global or local equilibrium, whereas in dynamic self-assembly, the systems of components dissipate energy to form and maintain patterns or structures that may be far from equilibrium. An example of static self-assembly is molecular crystallization, and an example of dynamic self-assembly is cell sorting in embryos. In general, dynamic self-assembly systems tend to be more complex than static self-assembly systems. Typically, the components' behaviors (e.g., their binding preferences) are not static but change in response to interactions with other components or the environment. For biological systems, the characteristics of their components undergo evolution as the patterns and structures resulting from the interactions among components are selected for specific functions (Caspar 1966; Sendova-Franks and Franks 1999; Anderson et al. 2002).

Researchers are working toward a more unified theory of self-assembly and a deeper understanding of its elementary functions and limits.

One such attempt is to view self-assembly processes as computations and vice versa. For example, it has been found that systems based on DNA tiles that implement such algorithmic self-assembly can perform Turing-universal computation.

Until now, self-assembly has most widely been applied in the synthesis and fabrication of products from molecular components. However, the potential of self-assembly processes with mesoscopic to macroscopic components is recognized (Whitesides and Boncheva 2002; Groß and Dorigo 2008). At these scales, the characteristics of the components can be precisely controlled and the self-assembly processes can be easily monitored. Potential applications include crystal synthesis with nanometer- to centimeter-scale components, fabrication of electrically or optically functional devices, and autonomous robots with adaptive body plans and functionalities.

Synonyms

[Self-organization](#)

Definition

Self-assembly is the process by which certain kinds of molecules in solution are able to associate into larger, more complex structures stabilized by hydrogen bonding and other generally non-covalent interactions.

Overview

The four forces that stabilize the structures of biomolecules are covalent bonds, hydrogen bonds, electrostatic interactions, and the hydrophobic effect. The synthesis of covalent bonds requires a significant expenditure of energy and is not usually associated with self-assembly processes, which are low energy reactions that occur spontaneously without a direct input of metabolic energy. An example of self-assembly is the formation of secondary and tertiary structure of proteins, in which hydrogen bonding is essential. For instance, when peptide chains are synthesized by ribosomes, portions of the growing strand form hydrogen-bonded alpha helices and planar structures called beta sheets. These structures arise spontaneously and are dominant features of

most proteins. Another fundamental biological structure stabilized by hydrogen bonds is the ► [double helix](#) of DNA, in which adenine is paired with thymine with two ► [hydrogen bonds](#), and guanine paired with cytosine with three hydrogen bonds. These are now referred to as Watson-Crick base pairs and more generally as complementary base pairing. If a DNA double helix is separated into single strands, for instance, by heating, upon cooling the two strands reassemble into the original double-helix structure.

A self-assembly process also produces lipid bilayers, the structural barriers composing all cell membranes. The primary contribution to bilayer assembly and stability is the hydrophobic effect that arises from the interaction of hydrocarbon chains with water. If a hydrocarbon chain is inserted into an aqueous bulk phase, the water molecules form orderly cage-like structures around the chain, which decreases the overall entropy of the system. However, if the hydrocarbon chains leave the surrounding water and associate into lipid bilayers, the orderly water-cage structures disperse and entropy of the system increases. The entropy-driven hydrophobic effect also contributes to the folding of protein chains into stable tertiary structures, in which nonpolar amino acids tend to reside in the protein molecule interior, with polar and ionic amino acids lining the surface.

Molecular assemblies stabilized by hydrogen bonding and the hydrophobic effect likely contributed to the increasing complexity of prebiotic structures required for the origin of cellular life.

Definition

Self-replication is the property for a system to build a functional and independent copy of itself.

Overview

Self-replication is a general concept that applies to systems of different nature (physical or theoretical) and of different scale (microscopic or macroscopic). It relies on the existence of an internal mechanism for the duplication of the full system. This implies the ability for the duplication mechanism to make a copy of itself. The replicated system becomes a fully functional entity, separated from the parent system, possessing the same properties. Namely, it must be able to replicate itself again. A minimal self-replicative system can be reduced to this sole function, in which case it can do nothing but generate copies of itself – whose function, thus, will be to generate more copies. More complex systems can perform additional functions. In this case, the replicative system must be able to reproduce not only itself but also all the additional mechanisms, so that the replicate can behave similarly to its parent.

Different levels of self-replication can be identified, depending on their accuracy. There can be very strict self-replication systems, producing a copy that is identical to the parent. This is, for example, the case of template ► [autocatalysis](#), where a molecule is able to directly catalyze the formation of an identical molecule (Plasson et al. 2011). More tolerant self-replicating systems allow the possibility of imperfect duplication. This is typically the case for biological systems based on ► [nucleic acid](#) replication, where point ► [mutations](#) are possible, slightly modifying the outcome. Such “general autocatalysis” (Muller 1922) is necessary for the evolution of the system (Vasas et al. 2010). An example of a minimalistic evolvable self-replicative system is the ► [prion](#), an infectious protein that is able to communicate its conformation to normal proteins, which in turn become infectious (Li et al. 2010). In the case of macroscopic systems, the replicate cannot be

strictly identical to the parent – molecule wise – but only similar to it. Such imperfect self-replication can be referred to as reproduction, which is typical of all living beings (Sipper 1998). In this case, the replicate globally possesses the same properties and characteristics as the parent, but is compositionally slightly different.

Key Research Findings

Self-Replication in Life

The self-replication of living organisms is based on genetic ► [replication](#). Each individual is a complex system, able to perform a large set of actions, among which is the ability to produce offspring. The mechanisms for the replication exist at several levels, but all of them are ultimately coded in DNA, bearing all the genetic information. At the molecular level, proteins enable the replication of the DNA molecules, themselves responsible for the synthesis – among other functions – of the replication proteins. At the cellular level, self-replication occurs by the division of one cell into two distinct ones, each containing the same kind of compounds and structures. At the individual level, self-replication is obtained either by division of the being or – in the case of sexual reproduction – by formation and fusion of gametes, each of which contains all the information and tools necessary for building a fully grown organism. Self-replication can ultimately be found at the level of colonies, where a limited number of individuals can separate from the parent colony to grow a new one. At each level, different accuracy of replication exists: DNA is copied with point mutations, crossover mechanisms generate genetic exchanges between chromosomes, sexual reproduction enables reshuffling of genes, etc. This property is crucial for enabling the key property of life, open-ended evolution, rather than endless duplication of identical objects.

Self-Replication in Artificial Life

Self-replication is one of the most fundamental studied properties of all living beings (Sipper 1998). ► [Artificial life](#) describes a minimalistic

theoretical representation of life, in order to understand its specific properties.

Self-replication by a cellular automaton is the first model to have been developed, initiated in the 1940s by von Neumann (1966). Such a system is composed of several cells that are disposed in a grid that can be of multiple dimensions. All cells can be in different states. A set of rules describes how each cell changes from one state to another after a given time step, depending on their present state and their environment. Some of these systems are prone to self-replication; this is typically the case for Langton's self-replicating loop (Langton 1984). This cellular automaton is based on a two-dimensional space, with eight-state cells. An initial 86-cell structure, disposed as a closed loop, is able to duplicate itself and generate a second identical 86-cell loop. ► [Cellular automata](#) can possess simple replicative structures, but can be more complex and replicate additional features. For example, the Tempesti self-replicating loop is similar to the Langton loop, as it is able to self-replicate in a similar fashion, but it additionally possesses a program that is automatically activated: once duplicated, the replicated loop is able to write inside itself the same encoded text than the one of its parent (Tempesti 1995).

Some computer programs are also able to self-replicate. In the 1980s, Core Wars, a computer game initially developed by Dewdney (1984), enabled the creation of programs that fight against each other in a computer environment. The purpose of this game is the destruction of the other programs and the domination of the virtual area. Some programs were successfully able to proliferate thanks to their self-replicating abilities. In more recent software, like Tierra (Ray 1994) or Avida (Lenski et al. 2003), the programs are even prone to open-ended evolution. Computer viruses are malicious application of self-replicating programs. Once designed, they are able to make copies of themselves and propagate inside a computer or from one computer to another via the network or physical media. They are, however, unable to evolve without direct intervention by their programmers (Lenski et al. 2003).

Some computer models intend to reproduce systems that are closer to biological systems.

The purpose is not only to investigate the property of self-replication per se but to understand the process of self-replication as it is implemented in life (Bersini 2010). The first system described in this spirit is the chemoton of Gánti (1975). This model is a minimalistic chemical representation of a cell that is able to maintain its activity and to self-replicate. It contains three interconnected autocatalytic cycles: (1) a metabolic subsystem responsible for the building of the other subsystems, (2) an information subsystem responsible for the system's self-replication, and (3) a membrane subsystem encompassing these subsystems and keeping the compounds within one system. These three subsystems are able to grow altogether, until the point where the whole system can divide to give birth to two separated complete systems.

Kinetics of Self-Replication

The self-replication of a system A corresponds formally to a $A \rightarrow 2A$ transformation: starting from one system, two identical or similar systems are obtained. Such a pattern can be referred to as autocatalysis, in analogy with chemical autocatalysis (Muller 1922). Different kinetic behaviors depending on the kinetic *order* of the autocatalytic mechanism can be observed for the evolution of self-replicating systems (Plasson et al. 2011). This results in different efficiency for their ability to compete with other self-replicating systems. Such dynamics are classically studied in population evolution (Nowak 2006). An *order* smaller than one generates a sub-exponential evolution characterized by the coexistence of all competing self-replicating systems ("survival of all"). First-order kinetics generates an exponential evolution characterized by the proliferation of the most efficient replicator ("survival of the fittest"). *Orders* larger than one generate hyperbolic evolutions characterized by the proliferation of the system initially present in larger quantity ("survival of the first").

The sub-exponential case, with an order inferior to one, is the least interesting, as it does not lead to a clear selective process. However, real mechanisms that seem to possess first-order kinetics may actually present a lower order. This is often the case for the replication of molecules by

template autocatalysis, in which the order falls to one-half on account of the high stability of the dimeric intermediate, which is actually a necessary condition for the selectivity of template replication (Wills et al. 1998).

Future Directions

The elaboration of theoretical self-replicating agents is a way to investigate the possibility for life to emerge from simple chemical systems. Typically, self-replicating programs can spontaneously emerge from an initially random setup. Koza investigated this by letting random programs evolve described by a computationally complete set of functions. He observed a probability of the order of 10^{-6} – 10^{-9} for obtaining the emergence of a self-replicative program that is then able to proliferate as soon as it appears (Koza 1994). In that spirit, designing a simple molecular replicator, able to proliferate without external help, would be a good indication of the possibility of the emergence of molecular replicators on the primitive Earth. Simple oligonucleotide (von Kiedrowski 1993) and oligopeptide (Lee et al. 1997) replicators have been successfully described in the literature. However, template replicators imply the formation of stable dimeric intermediates, leading to a parabolic evolution that undermines their ability to replicate efficiently (Wills et al. 1998). More recent work is oriented toward the design of more complete systems (Szostak et al. 2001), in the spirit of Gánti's chemoton (Gánti 1975). These take into account the necessity of energy transfer for efficient metabolism and for a membrane to enclose the system, in addition to the replicating mechanism itself. Ultimately, and beyond the relevance to the ► [origin of life](#), complete and autonomous self-replicating machines might be engineered (Freitas and Merkle 2004).

Cambridge, MA, USA

Keywords

Autocatalysis · Cross catalysis · Informational molecule

Definition

Self-replication in astrobiology refers to the ability of a chemical system to make copies of itself without the need for external instructions. The emergence of self-replication is considered to be a necessary step for the origin of ► [life](#).

Overview

Self-replication occurs when an informational molecule (such as a ► [nucleic acid](#)) directs the spontaneous synthesis of a copy of itself. Mechanisms for self-replication can be autocatalytic, where a molecule acts as a template to make a direct copy of itself, or cross-catalytic, where two or more molecules of different informational contents amplify one another. Modern life forms use a complex cross-catalytic mechanism of replication that involves the participation of protein molecules that catalyze the replication of the informational polymer (nucleic acids), which are also involved in the synthesis of the catalysts themselves. Primordial life, however, could have used simpler mechanisms for replication. Nucleic acids are informational polymers that form double-

stranded duplexes following the Watson-Crick base pairing rules and have the intrinsic potential to achieve self-replication via either one of the two previously mentioned mechanisms. This property is central to the RNA world hypothesis for the origin of life (Gilbert [1986](#)). Self-replication is not restricted to nucleic acid polymers, and it has been demonstrated to occur with other types of molecules such as peptides and other non-biological organic compounds.

Experimental approaches for the study of self-replication were initially focused on RNA template-directed polymerization reactions. This work showed that fully complementary polynucleotide duplexes are accessible starting from a single-stranded RNA ► [oligomer](#) (template) and energetically activated ribonucleotide monomers. The efficiency of the polymerization chemistry, however, is dependent on the nucleotide composition of the template, and the rates of polymerization are slow and similar to rates of RNA hydrolysis (Orgel [1992](#)). These combined difficulties have prevented the realization of complete replication cycles of RNA.

The first working example of a self-replicating molecule was obtained with a designed system consisting of two modified trinucleotide oligomers that upon ligation yield a product that could act as a template (catalyst) for a ligation reaction that results in the formation of more copies of itself (von Kiedrowski [1986](#)). This demonstration of autocatalytic self-replication indicated the feasibility of such systems but suffered from product inhibition of autocatalysis as a consequence of duplex formation. Improvements on these model systems were later obtained with variations on the chemistry of the building blocks (Zielinski and Orgel [1987](#)). Examples of self-replication using more complex-designed cross-catalytic molecular systems have also been achieved (Sievers and von Kiedrowski [1994](#)). The use of non-nucleoside building blocks in self-replication studies has improved both the efficiency and our understanding of autocatalytic processes (Tjivikua et al. [1990](#); Terfort and von Kiedrowski [1992](#)). Peptides and supramolecular assemblies of organic molecules represent alternatives to nucleic acid-based self-replication and

have interesting implications in astrobiology due to the different nature of their chemistry (Lee et al. 1996). Despite the interest and effort in this area of research, a robust self-replicating system that can undergo Darwinian evolution has not been experimentally obtained. Current efforts toward that goal are mainly focused in chemical replication studies (Schrum et al. 2009) and in vitro evolution experiments (Lincoln and Joyce 2009).

Self-Shielding Effects on Isotope Fractionation

Ko Hashizume

Keywords

Photochemistry · Photodissociation · Mass-independent fractionation

Synonyms

[Isotope-selective photolysis](#); [Self-shielding](#)

Definition

The self-shielding effect is a phenomenon expected to occur in a gas medium illuminated by a light source, when a molecule in the gas absorbs light with a particular wavelength that may result in its dissociation. The light of this wavelength is gradually attenuated as it travels

through the gas medium, leading to a decreased photodissociation rate of the target molecule. The attenuation rate of the light depends on the abundance of the molecule. When molecules with different combinations of isotopes are photodissociated by different wavelengths, this effect may cause an abundance-dependent isotope fractionation, as opposed to the common mass-dependent fractionation.

Overview

The self-shielding effect may occur when the following conditions are met. (1) Line absorption: The absorption of the photodissociating light occurs only at a narrow range of particular wavelengths. (2) The light with the wavelength of interest reaches to the target molecule, that is, the wavelength is sufficiently intense in the light source and is not shielded by other reasons, for instance, by absorption by other species. Isotope fractionation by the self-shielding effect may occur when the following condition is additionally met. (3) The wavelengths of the photodissociating light for different isotopologues are separated by more than both the abovementioned admitted range and the Doppler width. The fractionation may occur at a certain distance from the edge of the gas medium, determined by the photodissociation cross section and the column density of the isotopologue with the largest abundance.

The self-shielding effect on isotope fractionation was first proposed to occur in a ► [molecular cloud](#), possibly irradiated by ultraviolet (UV) light emitted from a nearby young star (Bally and Langer 1982). They discovered that relative abundances among the isotopologues of carbon monoxide show peculiar variations at a certain distance from the edge of the molecular cloud. Comparing the abundances of $^{12}\text{C } ^{16}\text{O}$, $^{13}\text{C } ^{16}\text{O}$, and $^{12}\text{C } ^{18}\text{O}$, after correction for a possible chemical fractionation, they deduced that $^{12}\text{C } ^{16}\text{O}$, the dominantly abundant isotopologue, was enriched about twice as much as the others. They explained

this observation by the self-shielding effect associated to the isotope-selective photodissociation of CO molecules that may occur upon line absorption of UV.

The same type of isotope fractionations for carbon monoxide and possibly molecular nitrogen is predicted to have occurred in our solar system, in the early solar nebula or in the ancestral molecular cloud, which could be recorded in planetary solid materials. Note that it is not the isotope composition of the gas species (CO or N_2) that could be recorded among the planetary materials but the composition of the photodissociated products. A viable prediction model must contain a reasonable process to accommodate the isotope record of the products into stable compounds, i.e., cold traps. The cold traps proposed are oxides and nitrides (Clayton 2002), or water and organics (Yurimoto and Kuramoto 2004; Lyons and Young 2005), depending on the proposed place (temperature) for the self-shielding effect to have occurred.

Serine

Kensei Kobayashi

Yokohama National University, Yokohama, Japan

Definition

Serine is one of the 20 protein amino acids whose chemical structure is $\text{NH}_2\text{CH}(\text{CH}_2\text{OH})\text{COOH}$ (Fig. 1). Its three-letter symbol is Ser and one-letter symbol is S. Since serine has a hydroxyl ($-\text{OH}$) group in its side chain, it is classified as a polar amino acid. Its molecular weight is 105.09, and its isoelectric point is 5.68. Serine is present in the active sites of many enzymes such as proteases and is widely distributed in the biosphere. Serine, together with glycine, is a predominant amino acid in the hydrolysate of human fingerprints. In the early analyses of carbonaceous chondrites, serine was one of the most abundant amino acids, but later it was found that most of this

Serine, Fig. 1 Serine

amino acid detected was a terrestrial contaminant. In recent amino acid analysis of carbonaceous chondrites, a number of indigenous amino acids were detected, but serine was not common among them. Recently serine was identified in Antarctic carbonaceous chondrites.

Serpentine

Stephane Guillot
LGCA, Universite de Grenoble, St Martin
d'Hères, France

Definition

Serpentine is a hydrous magnesium-iron phyllosilicate having the chemical formula $(\text{Mg, Fe})_6(\text{OH})_n\text{Si}_4\text{O}_{10}]$. It is greenish, opaque to translucent, light (density of 2.6 g/cm^3), soft (hardness <4) with a greasy luster. All occurrences are microcrystalline and massive in habit, never being found as single crystals. There are three mineral polymorphs: antigorite, chrysotile, and lizardite. Antigorite is stable at high temperatures ($400\text{--}700^\circ\text{C}$) at great depths. Lizardite and chrysotile typically form near the Earth's surface and break down at relatively low temperatures, below 400°C . Asbestos is a fibrous form of serpentine. Serpentine is the hydrous breakdown product of olivine or – more rarely – orthopyroxene. During hydrolysis of the ferromagnesian minerals contained in ultramafic rocks and the formation of serpentine (serpentinization), large amounts of H_2 gas, CH_4 gas, and alkaline solutions are produced. These products possibly made the sites of active serpentinization (around submarine hydrothermal vents) favorable environments for the development of chemotrophic

organisms on the early Earth. It has also been speculated that serpentinization made possible through hydrous alteration of basaltic oceanic crust facilitates subduction. This, in turn, made plate tectonics and crustal segregation by continental growth possible.

Hydrothermal vents · Methane · Ultramafic
rocks

Definition

Serpentinization is the process of hydrothermal or metamorphic alteration transforming Fe-Mg-silicate minerals, typically ▶ [olivine](#), but also pyroxene, or amphiboles from ultramafic rocks into serpentine minerals which is a subgroup of phyllosilicates (sheet of silica tetrahedra) of general formula $(\text{Mg, Fe, Ni})_3\text{Si}_2\text{O}_5(\text{OH})_4$. Serpentinite is a rock dominated by a family of soft ductile minerals, notably antigorite and lizardite. Its presence in the mantle wedge helps lubricate the subduction of the oceanic plate. Serpentinization of ultramafic oceanic crust forms hydrogen, methane,

and ammonia. These gases are observed in the hydrothermal springs of the ► [mid-ocean ridges](#) and in ophiolites. The pH of these hydrothermal fluids is generally low at depth, but at low temperature, may be high enough to favor amino acid activity and maintain an environment compatible with life.

Overview

The process of serpentinization has received much attention by astrobiologists as being a geological process able to furnish a “sustained source of chemically transducible energy” (Russell et al. 2010) and raw material to sustain the emergency of life (Schulte et al. 2006; Schrenk et al. 2013).

Interaction between the ferrous component of olivine (fayalite) present in the ultramafic oceanic crust releases hydrogen (H₂) according to the reactions:

The silica liberated in the process reacts with forsterite (Mg-olivine, Mg₂SiO₄) to form serpentine (2Mg₃Si₂O₅(OH)₄) according to (Barnes and O’Neil 1969):

When CO₂ is present, methane can be formed through the following reaction:

A similar reaction with nitrogen produces ammonia. The process of serpentinization around submarine hydrothermal vents where ultramafic rocks react with heated seawater to form serpentine creates favorable environments for organisms using reduced species such as H₂ and CH₄ as a source of

energy (chemotrophy), rather than sunlight in the Hadean ocean. Further reaction with cations of seawater provides an abundant source of protons (H⁺) which could have been used by first organisms for the synthesis of ATP (Russell et al. 2010).

Serpentinization is also an alternative pathway to produce abiotically complex organics in the Hadean ocean, such as methane, n-alkanes, and potentially simple organic acids and N-bearing compounds, as presently observed in abundance in smokers’ effluents. Hydrogenocarbonate is reduced by hydrogen to formate or acetate (Lang et al. 2010) according to:

Reduced carbon species (graphite) produced during the early abiotic stages of serpentinization of ultramafic rocks show isotopic compositions (δ ¹³C from −15‰ to −50‰) mimicking those of organic compounds (McCollom and Seewald 2006; van Zuilen et al. 2002; Lopez-Garcia et al. 2006). These isotopic compositions overlap with those observed in several putative traces of life in Archean rocks, clearly indicating that the isotopic composition of carbon cannot be used alone for determining the biogenicity of those findings. However, the presence of reduced carbon species related to serpentinization is a valuable tracer of chemical activity sustaining chemosynthetic life.

Serpentinization (Mars)

Vlada Stamenković
Earth, Atmospheric and Planetary Sciences,
Massachusetts Institute of Technology (MIT),
Cambridge, MA, USA

Keywords

Geochemical reaction · Hydrothermal vents · Mars · Methane of Mars

Definition

Serpentinization is the reaction of ultramafic (high in magnesium and iron) ► [minerals](#) with ► [water](#), occurring especially in olivine ($[(\text{Mg}, \text{Fe})_2\text{SiO}_4]$) as well as in pyroxenes (mostly $[(\text{Mg}, \text{Fe})_2\text{Si}_2\text{O}_6]$). The reaction occurs below a critical temperature of about 500–700 K (Oze and Sharma 2007) in the crust and upper mantle of Earth and possibly Mars. Below temperatures of 500 K, the reaction rate decreases rapidly (Martin and Fyfe 1970), although the dependence of the reaction rate on temperature is not well quantified. The hydrated minerals that are formed by serpentinization are called ► [serpentes](#) and contain hydrous magnesium iron phyllosilicates ($[(\text{Mg}, \text{Fe})_3\text{Si}_2\text{O}_5(\text{OH})_4]$), whereas ► [rocks](#) containing serpentes are called serpentinites.

Overview

Serpentes have been detected on Mars by the CRISM spectrometer on the Mars Reconnaissance Orbiter (MRO) (Ehlmann et al. 2009). Serpentinization has been suggested to explain the yet inconclusive and debated observations of ► [methane](#) in the Martian atmosphere (Mumma et al. 2009; Zahnle et al. 2011). It is furthermore speculated to potentially create locally habitable conditions for microorganisms, analogous to hydrothermal vent systems like Lost City near the Mid-Atlantic Ridge at the Atlantis massif on ► [Earth](#) (Kelley et al. 2005). Serpentinization might help to sustain ecological niches by providing heat and ► [hydrogen](#) to be used by autotrophic organisms. Hydrogen released during serpentinization can react with dissolved ► [carbon dioxide](#) in a ► [Fischer-Tropsch-type reaction](#) to produce higher hydrocarbons such as methane, the main nutrient for methanotrophs. But the hydrogen and heat generation rates both depend on the amount of water present, the ambient temperature, and the magnesium number of the reacting mineral. Because of the similar size of magnesium and iron ions, olivine can contain arbitrary magnesium-to-iron ratios, described by the magnesium number x_{Mg} of the reacting

mineral $x_{\text{Mg}} = \frac{\text{mol}(\text{Mg})}{\text{mol}(\text{Mg}) + \text{mol}(\text{Fe})}$. Below are the typical olivine end-member serpentinization reaction for fayalite ($[\text{Fe}_2\text{SiO}_4]$, $x_{\text{Mg}} = 0$) and forsterite ($[\text{Mg}_2\text{SiO}_4]$, $x_{\text{Mg}} = 1$) at $T_0 = 298 \text{ K}$ and $p_0 = 1 \text{ bar}$ and associated Gibbs energies found by Oze and Sharma (2005):

Hydrogen is only produced when iron is present, resulting in the formation of magnetite $[\text{Fe}_3\text{O}_4]$ and quartz $[\text{SiO}_2]$ for fayalite serpentinization. Further analysis (Oze and Sharma 2007) shows that both, the Gibbs energy and the enthalpy, are negative and minimal at large magnesium contents and become positive for x_{Mg} between 0.25 and 0.5 (depending on temperature), making the reaction thermodynamically not favorable and endothermic (heat consuming). The observed magnesium of Martian olivine is lower than on Earth between $0.3 < x_{\text{Mg}} < 0.7$ (Hoefen et al. 2003) but still large enough to provide hydrogen and heat on Mars if enough subsurface water is present.

SETI

David W. Latham
Harvard-Smithsonian Center for Astrophysics,
Cambridge, MA, USA

Synonyms

[Search for extraterrestrial intelligence](#)

Definition

SETI, the Search for Extraterrestrial Intelligence, is an exploratory science that seeks evidence of life in the universe by looking for some signature of its technology. See SETI (the SETI Institute) for more details.

Overview

Are there any technical civilizations out there? Do we have the technology to detect their signals? What would be the most efficient way to decipher their messages? The answers to these questions make the foundation of SETI.

Modern attempts to detect extraterrestrial signals date back half a century, to project Ozma in 1960. Early searches focused on the microwave region of the radio spectrum, where there is minimum interference from natural sources in the Galaxy. From those early beginnings, enormous improvements were achieved in the coverage of radio frequencies and area on the sky, but vast regions of search space remained unexplored. With time, new developments in our own technological capabilities suggested alternative strategies for communication, such as nanosecond optical laser pulses aimed very precisely in extremely narrow and efficient beams.

In the 1980s, NASA became involved in an ambitious SETI program with two prongs; an all-sky survey and a targeted search. The search was mainly in the radio domain, until the congress defunded the effort, just a year after Carl Sagan pushed the ceremonial key in 1992 to initiate the search at the Arecibo Observatory in Puerto Rico. Aside from this program, most of the interest in and support for SETI has come from the public, through a wide variety of initiatives. A pioneering effort by SETI@home harnessed the power of millions of underused computers around the world to analyze data acquired serendipitously with the Arecibo telescope. The Planetary Society supported powerful new searches in both the radio and the optical, and papers reporting null results appeared in professional publications such as the prestigious *Astrophysical Journal*. Despite the lack of success to date, SETI continues in two major directions; Research and Development (R&D) and Projects. R&D efforts include the development of new signal processing algorithms, new search technology, and new SETI search strategies that are then incorporated into specific observing projects.

History

The history of SETI (Search for Extraterrestrial Intelligence) began with the 1959 Cocconi and Morrison paper published in *Nature*, entitled “Searching for Interstellar Communications”, establishing the feasibility of interstellar signaling by radio waves. Their authors, the physicists Giuseppe Cocconi (1914–2008) and Philip Morrison (1915–2005) (Cornell University, USA), suggested that the spectral frequency of 1,420 MHz (or 21-cm emission, corresponding to the famous hyperfine line of neutral hydrogen) could be used as the preferential frequency for communication in the Galaxy. In the mean time, radio astronomers were testing the possibilities afforded by a new generation of devices. In such a context, listening to other star systems in the hope of catching artificially produced signals appeared as an exalting challenge.

Independently, the radio astronomer Frank D. Drake (1930–) (Cornell University, USA) was fascinated by the possibility of communicating with other intelligences in the Galaxy. He became the first to test the Cocconi and Morrison hypothesis, at the National Radio Astronomy

Observatory (NRAO) in Green Bank (West Virginia, USA). Drake's project Ozma (named after the fictional Princess Ozma in L. Frank Baum's *Land of Oz*) began in April 1960 when he pointed the 85 ft diameter antenna at two nearby Sun-like stars (Epsilon Eridani and Tau Ceti). Two hundred hours were dedicated to Project Ozma, but, as confirmed by Drake himself, "no signals of extraterrestrial origin were discovered during these preliminary observations."

The year after, a meeting held at Green Bank established SETI as a scientific discipline. During this event, Drake proposed a formula that came to be best known as the ► ["Drake equation"](#), which was supposed to provide a framework to estimate the number of technological civilizations capable of communicating in the Galaxy.

Directly linked to this formula, the ► ["Fermi Paradox"](#) stated that if such extraterrestrial civilizations were existing, they should have mastered space travel and have already undertaken the colonization of the Galaxy (including the Earth). Since there was no evidence of any visit of extraterrestrials to Earth, the (pessimistic and questionable) conclusion was obvious: No other technological civilization could be present in the Galaxy.

No matter what this paradox suggested, concrete SETI programs have been undertaken from the late 1970s up to now (Sentinel, META, BETA, SERENDIP, southern SERENDIP, Phoenix, Optical SETI, Argus, ATA) and successively carried out, in spite of strong difficulties about funds.

Definition

Sagittarius B2 (Sgr B2) is an exceptionally massive ($8 \times 10^6 M_{\odot}$; Schmiedeke et al. 2016) giant ► [molecular cloud](#) located ~130 pc (Reid et al. 2009) from Sgr A* – the Milky Way Galaxy’s central supermassive ► [black hole](#) – which is at a distance of ~8.5 kpc from Earth (Genzel et al. 2010). Sgr B2 is within the Central Molecular Zone (CMZ) of the Galaxy, a ~300 pc radius region around Sgr A* that exhibits widespread emission from ► [complex organic molecules](#) (COMs). The Sgr B2 cloud is highly heterogeneous and composed of both compact (hot) and extended (cold) molecular material, molecular ► [maser](#) regions, and ultracompact continuum sources (Remijan et al. 2014).

History

In terms of its astrobiological relevance, Sgr B2 is the preeminent source for the detection and study of new molecules in the ► [interstellar medium](#)

(Remijan et al. 2014). The first interstellar detections of polyatomic molecules including ► [ammonia](#) (NH₃) and ► [water](#) (H₂O) were toward Sgr B2 (Cheung et al. 1968; Cheung et al. 1969). Since that time, study of the region has resulted in the detection of a number of biologically relevant molecules; many of these detections have been the result of extensive ► [molecular line surveys](#) which have been conducted toward the region with a wide variety of facilities, including the Green Bank Telescope, the Herschel Space Telescope, and the Atacama Large Millimeter Array (► [ALMA](#)), with nearly continuous frequency coverage from ~5 to 1,900 GHz (see, e.g., Neill et al. 2012 [1–50 GHz], Turner 1991 [70–115 GHz], Nummelin et al. 1998 [218–263 GHz], Csengeri et al. 2014 [315–375 GHz], Neill et al. 2014 [480–1910 GHz]).

Overview

Structure

Sgr B2 has a complex physical structure with cores of star formation embedded in an extended envelope. Molecular, atomic, and ionized gas have been observed in the extended envelope, appearing without obvious spatial separation between the three phases of gas (Goicochea et al. 2003; Jones et al. 2008). Three main cores of star formation have erupted, namely, the North, Main, and South cores. More than 200 sources with compact, cometary, and shell shapes have been identified in and close to the core, consisting of a mix of H II regions and young stellar objects (Ginsburg et al. 2018). All known molecular masing transitions are detected in Sgr B2, with each transition typically detected at multiple positions near the cores of Sgr B2 (Mehring and Menten 1997; Hoffman et al. 2007). At submillimeter wavelengths, two continuum sources composed of 20 substructures are present in the North core of Sgr B2 (Sgr B2(N)), and a clumpy structure composed of up to 27 components is detected in the main core (Qin et al. 2011, Sánchez-Monge et al. 2017). The submillimeter continuum emission is produced by warm dust in environments with high densities. One of the sub-mm peaks

corresponds to the position of the so-called Large Molecule Heimat, the preeminent source of molecular line emission.

As the most massive known molecular cloud in the Galaxy, Sgr B2 is accessible only at X-ray and radio to far-infrared wavelengths. Sgr B2 is known to have an unusually high flux of X-ray radiation. As no compact X-ray source is observed in Sgr B2, the X-ray radiation is understood as evidence for highly elevated X-ray emission from Sgr A* 300–400 years ago, making Sgr B2 an X-ray ► [reflection nebula](#) (Terrier et al. 2010). Like most clouds in the CMZ, the gas exhibits supersonic turbulence and widespread shocks. The cosmic ray ionization rate is observed to be an order of magnitude higher in Sgr B2 than in most Galactic molecular clouds (van der Tak et al. 2006), and observations of Zeeman splitting of the 21 cm spin-flip transition of HI indicate a high magnetic field strength (Crutcher et al. 1996). Given these conditions, Sgr B2 is regarded as the only Galactic source with an environment analogous to the central regions of starburst galaxies.

Perhaps because of the unique physical environment in this cloud, Sgr B2 hosts the most diverse molecular chemistry observed anywhere outside the solar system.

Chemistry

Indeed, the majority of COMs detected outside our solar system have been detected toward Sgr B2, often exclusively toward this source (Menten 2004). This rich chemical complexity is likely the result of the unique physical conditions that produce favorable conditions for both production and detection of a wide range of COMs. Among the species detected are ► [amines](#), ► [amides](#), cyanides, saturated and unsaturated molecules, alcohols, ► [aldehydes](#), ► [ethers](#), ► [esters](#), ► [carboxylic acids](#), ketones, and epoxides. Of particular interest for astrobiology are the detections of the simplest sugar-related species, ► [glycol-aldehyde](#) (CH_2OHCHO ; Hollis et al. 2004), the first interstellar molecule detected with a branched carbon backbone: *iso*-propyl cyanide ($\text{C}_3\text{H}_7\text{CN}$;

Belloche et al. 2014), and the largest interstellar molecules to possess a peptide bond: acetamide (CH_3CONH_2 ; Hollis et al. 2006) and urea (H_2NCONH_2 ; Remijan et al. 2014, Belloche et al. 2019). Observations using interferometric arrays have also characterized the spatial distribution of emissions from these and other COMs within this source in detail. For example, data from an ALMA survey show the spatial separations of selected $\text{C}_2\text{H}_4\text{O}_2$ isomers toward Sgr B2(N) (Xue et al. 2019). The distinct distribution of the COMs, as well as detections of complex species in both the cold extended envelope (e.g., formamide) and compact regions toward the ► [hot core](#) (e.g., acetamide), demonstrate both the spatial and chemical complexity of Sgr B2.

Shale

Nicholas Arndt
Emeritus Professor, ISTerre, University Grenoble
Alpes, Grenoble, France

Definition

Shale is a fine-grained ► [sedimentary rock](#) composed mainly of clay minerals (hydrous aluminum phyllosilicates) with minor proportions of ► [quartz](#), feldspar, calcite, and iron oxides. Because of its small grain size, the constituent particles can settle only in water free of turbulence. This is only the case in nearly stagnant water bodies. Shale is thus deposited in closed basins, estuaries, lakes, and similar depositional settings protected from currents, waves, and wind and in deep water far from continents. Varieties rich in organic material, called black shales, provide valuable sources of information about the earliest forms of life and serve as petroleum source rocks. Shale is converted by ► [metamorphism](#) into mica schist. The occurrence of shale deposits in planetary surfaces would be a good indicator of the past presence of liquid water on their surfaces.

Synonyms

[Shark Bay microbialites](#); [Shark Bay thrombolites](#)

Definition

Stromatolites are microbially mediated sedimentary structures. The best-known examples are thriving in the shallow waters of Hamelin Pool at the southern end of Shark Bay in Western Australia. Among the first modern ► [stromatolites](#) to be described, the Shark Bay stromatolites provide insights to the biological and physical forces controlling stromatolite growth and are an important analog to ancient stromatolites. The Shark Bay structures include meter-sized, lithified, dome- and club-shaped structures forming at subtidal to intertidal water depths, as well as millimeter-sized, tufted microbial mats forming in the supratidal zone. The lithified stromatolites consist of very coarsely layered detrital sediment accreted over time through microbial trapping and binding of particles and carbonate precipitation.

Shepherding

Sean N. Raymond
Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

Shepherding is the process by which a much larger body constrains the motion of many much smaller objects. Thus, a migrating planet can push ► [protoplanetary disk](#) material inward along with it; in the context of a giant planet migrating toward its central star, ► [planetesimals](#) and ► [planetary embryos](#) can be shepherded by the giant planet via resonances and may enable the formation of close-in super-Earth planets. In planetary rings, small shepherding satellites can constrain the motion of ring particles and hence structure the appearance of the rings.

Shergottites

Ana-Catalina Plesa
Institute of Planetary Research, German
Aerospace Center (DLR), Berlin, Germany

Keywords

SNC meteorites · Rare Earth elements ·
Cosmic-ray exposure age · Noachian ·
Hesperian · Amazonian

Definition

Shergottites are a subgroup of the SNC meteorites named after the Shergotty meteorite. About 78% of the Martian meteorites are classified as shergottites.

Overview

The age of all shergottites has long been debated since some isotopic systems like Pb-Pb indicated an age between 4.1 and 4.3 Ga, corresponding to the Noachian period (e.g., Bouvier et al. 2009), but all other isotopic systems marked these rocks as young samples with ages between 165 and 475 Ma placing them in the late Amazonian epoch (e.g., Nyquist et al. 2001). A young age of shergottites led to a so-called “age paradox,” since young volcanic surfaces from which shergottites might have been ejected by impacts represent only about 20% of the Martian surface (Tanaka et al. 1988). Craters possibly representing the impact locations from which the shergottites were ejected have been identified on the young terrains in Tharsis and Elysium provinces (e.g., Tornabene et al. 2006). However, the Mojave crater, formed on a 4.3 Ga-old terrain, has been found to match the mineralogy of three shergottite samples, that is, Shergotty, Los Angeles, and QUE94201 (Werner et al. 2014). More recent U-Pb and Pb-Pb isotopic measurements, which were performed on the NWA 5298 sample, indicate the crystallization near the Martian surface at an age of 187 ± 33 Ma, and is consistent with a young age of the shergottites (Moser et al. 2013).

The shergottites can be divided into three petrological subgroups (basaltic picritic and lherzolitic shergottites) depending on their olivine content. Basaltic shergottites are rocks composed of pyroxene and plagioclase but do not contain olivine or chromite. Picritic or olivine-phyric shergottites are catalogued as extrusive pyroxene-plagioclase basalts with olivine megacrysts (large olivine crystals surrounded by finer-grained matrix). The third petrological subgroup is defined by lherzolitic shergottites, which are plutonic ultramafic rocks containing at least 40% modal olivine. Depending on the ratio LREE/HREE (light rare earth elements/heavy rare earth

elements) relative to CI chondrites, one can distinguish between depleted (highly depleted), intermediate (moderately depleted), and enriched (slightly depleted) shergottites. Although there are exceptions, most of the enriched shergottites are basaltic; intermediate samples are lherzolitic, while the picritic shergottites are usually depleted. The depleted shergottites have a LREE/HREE ratio close to $0.12 \times$ CI chondrites, while the enriched samples have a ratio close to $1.0 \times$ CI (Bridges and Warren 2006). These different subtypes of the shergottites are thought to hint at different reservoirs in the Martian mantle.

Shergotty

Ana-Catalina Plesa

Institute of Planetary Research, German Aerospace Center (DLR), Berlin, Germany

Definition

Shergotty is a 5-kg Martian meteorite discovered in 1865 in Shergotty (now Sherghati), India. It also names a subgroup of the SNC meteorites, the shergottites, representing 78% of the Martian meteorites. Its age has been dated to ca. 165 Ma, although initially Pb-Pb dating indicated an age as old as 4.3 Ga. Shergottite source craters have been identified on young terrains in Tharsis and Elysium provinces. Petrologically, *Shergotty* is a basaltic sample (containing pyroxene and plagioclase but no olivine or chromite), enriched in trace elements.

Washington, DC, USA
Georgia Institute of Technology, Center for
Chemical Evolution, Atlanta, GA, USA

Synonyms

[Shock front](#)

Definition

A shock wave is a type of propagating disturbance. Like other waves, it carries energy and

can propagate through a physical medium or, in some cases, in the absence of a material medium, for example, through an electromagnetic field. When an object or disturbance, such as a meteor entering the atmosphere of a planet and its concomitant shock wave, moves faster than its effects can be propagated into the surrounding fluid, fluid near the disturbance cannot change its properties before the disturbance arrives. In a shock wave, the properties of the fluid such as density, pressure, and temperature change almost instantaneously. The energy of a shock wave dissipates relatively quickly with distance.

Many types of shock waves are found in astrophysical environments. Some examples are shock waves accompanying supernovae or blast waves traveling through the interstellar medium and the bow shock front caused by the Earth's magnetic field colliding with the solar wind.

Shock, Interstellar

Steven B. Charnley
Solar System Exploration Division, Code 691,
Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Synonyms

[Shock front](#); [Shock wave](#)

Definition

A shock is a highly nonlinear compression wave in a medium, which may be a fluid or solid, where

the wave carries energy and where the physical parameters of the medium change abruptly. Astrophysicists recognize two types of shocks in the ► [interstellar medium](#), C type and J type. C-type shocks are supersonic, multi-fluid flow structures occurring in weakly ionized plasma in which the physical variables (density, temperature) undergo a *continuous* change over the scale of the flow. In this case, the speed of the disturbance, the shock speed, is less than that of the magnetosonic speed in the plasma. In contrast, a J-type shock is a supersonic flow structure in which the physical variables (density, temperature) undergo a discontinuous change (*jump*) at the shock front. In this case, the speed of the disturbance, the shock speed, is greater than that of the sound speed in the gas. Interstellar shocks are produced, for example, by the propagation of a ► [supernova](#) blast wave into the ambient medium.

Shocked Quartz

Philippe Claeys
Earth System Science, Vrije Universiteit Brussel,
Brussels, Belgium

Definition

Shocked quartz refers to quartz grains displaying microscopic defects in crystalline structure that were produced by the passage of high-velocity and high-pressure (>5 GPa) shock waves. Shock metamorphism is commonly illustrated in quartz by the presence of fine lamellae of amorphous SiO₂ oriented parallel to two (or more) specific crystallographic planes and called planar deformation features, or PDF. Under extreme pressure, the whole quartz crystal transforms to glass. Shocked quartz is a diagnostic criterion to recognize hypervelocity impacts. Indeed, there are no other natural geological processes (tectonics,

volcanism, etc.) capable of producing the required high-pressure dynamic shock waves. Shock features are common in impact crater rocks and in some meteorites. Shock metamorphism is also known in zircon, feldspar, and olivine.

Siderite

Daniele L. Pinti
Geotop, Research Centre for the Dynamics of the
Earth System, Université du Québec à Montréal,
Montréal, QC, Canada

Synonyms

[Iron carbonate](#); [Iron spar](#); [Spathose iron](#)

Chemical Formula

FeCO₃

Definition

Siderite is a carbonate mineral of the trigonal crystalline system. It forms mainly in sedimentary and hydrothermal environments and occasionally

in igneous pegmatite (pegmatite is an intrusive igneous rock with large, well-developed crystals). Siderite is found in banded iron formations of different ages, the oldest being at Isua, West Greenland (ca. 3.8 Ga). The occurrence of siderite is considered an index of intermediate oxidation conditions, compared to that in sulfide-facies (reducing conditions) and hematite- magnetite facies iron formations (oxidizing conditions). Being a carbonate, siderite is actively sought on planetary surfaces such as Mars as indirect evidence of the presence of water and mildly oxidizing conditions.

SiH₄

- ▶ [Silane \(SiH₄\)](#)

Silane (SiH₄)

William M. Irvine
Department of Astronomy, University of Massachusetts, Amherst, MA, USA

Synonyms

SiH₄; [Silicane](#); [Silicon tetrahydride](#)

Definition

Silane (SiH₄) is the silicon analog of methane (CH₄). The symmetry of its tetrahedral shape, with four equivalent hydrogen atoms, results in a zero electric dipole moment and hence no pure rotational transitions. Silane is a gas under standard laboratory conditions, where it is extremely flammable.

History

Astronomically, silane is observed in the envelopes of some evolved stars by means of infrared

transitions at a wavelength of about 11 μm . It is expected by chemical equilibrium arguments to be present in the deep atmospheres of Jupiter and other gas [▶ giant planets](#) (Visscher et al. 2010). The related molecular species methyl silane (CH_3SiH_3) and silyl cyanide (SiH_3CN) have been detected in the envelope of the carbon-star IRC+10216 (Cernicharo et al. 2017).

Definition

Silicate minerals are those minerals that contain $[\text{SiO}_4]^{-4}$ as the fundamental unit of their chemistry and structure. Any other chemical element may occur in silicate minerals. $[\text{SiO}_4]^{-4}$ is a tetrahedron containing the four oxygen atoms in the apices and the silicium atom in the center. Up to all four oxygen atoms may be shared with other tetrahedrons. The number of shared oxygen atoms and the final space distribution are used to classify the silicate minerals.

Overview

Despite the fact that silicate minerals may accommodate any chemical element in their structures, the most common elements found are Al, Mg, Fe, Ca, Na, and K. Al is a common substitute for Si in the silica tetrahedron. Table 1 shows the classification of silicates, including their basic tetrahedral structure and most common minerals.

The Earth's [▶ crust](#), upper [▶ mantle](#), and transition zone are essentially composed of silicate minerals. The crust is mainly composed of silicate minerals containing mostly Al, Ca, Na, and K, as quartz $[\text{SiO}_2]$, feldspar [alkali-feldspar (K, Na)(Al, Si) $_3\text{O}_8$, and plagioclase $\text{Na}(\text{AlSi}_3\text{O}_8)$ - $\text{Ca}(\text{AlSi}_2\text{O}_8)$]. Much less abundant but still widespread and important in the Earth's crust are Ca-, Fe-, and Mg-silicates,

Silicate Minerals, Table 1 Classification scheme of silicate minerals

Name	Basic Si-tetrahedra structure	Number of shared oxygens	Example of common minerals
Nesosilicates	Independent tetrahedra	0	Olivine
Sorosilicates	2 tetrahedra	1	Epidote
Cyclosilicates	Rings of 3, 6, and 4 tetrahedra	2	Tourmaline
Inosilicates	Single tetrahedra chain	2	Pyroxene
	Double tetrahedra chain	2 or 3	Amphibole
Phyllosilicates	Tetrahedra sheet	3	Mica
Tectosilicates	Tridimensional framework	4	Quartz, feldspar

for example, mica $[K_2(Al, Mg, Fe)_{4-6}(Al, Si)_8O_{20}(OH,F)_4]$, amphibole $[(Ca, Na)_{2-3}(Mg, Fe, Al, Ti)_5(Si, Al)_8O_{22}(OH)_2]$, and pyroxene $[(Ca, Na)_{1-p}(Mg, Fe)_{1+p}(Al, Si)_2O_6(0 < p < 1)]$. Earth’s upper mantle and the transition zone are largely composed of the following Ca-, Mg-, Fe-bearing silicate minerals: olivine $[(Mg, Fe)_2SiO_4]$, pyroxene (see above), and garnet $[(Ca, Mg, Fe)_3Al, Fe, Cr, Ti)_2Si_3O_{12}]$. Chemical elements inside parenthesis in the chemical formulas occupy the same structural site and may vary in proportion one to another in a replacement process. Whenever valences are different, a conjugate elemental substitution occurs to compensate charge imbalance. The chemical element substitutions characterize these minerals as solid solutions. Extreme chemical compositions are called “end members.” Each end member has a specific name, as for example “diopside” for the pyroxene end member $CaMgSi_2O_6$.

Definition

Silicon (Si) is an element present in all natural environments, including the biosphere. It has three stable isotopes of mass 28, 29, and 30, respectively. Its isotopic composition is expressed in the delta notation $\delta^{30}Si$ ($^{30}Si/^{28}Si$) and $\delta^{29}Si$ ($^{29}Si/^{28}Si$) in per mil units normalized to a standard reference (see “► [Delta, Isotopic](#)”). The $\delta^{30}Si$ and $\delta^{29}Si$ vary in the solar system by up to 14‰ and 7‰, respectively. These isotopic changes in Earth and extraterrestrial materials are used to constrain diverse processes such as the origin of the ► [solar system](#), the protosolar nebula condensation, the core-mantle segregation, the appearance of life, the origin and growth of continental crust, the temperatures of early oceans, the weathering of silicate rocks, or the role of siliceous organisms in C-Si cycles.

Overview

The potential role of silica (SiO_2) in the emergence of life has been often questioned, especially because SiO_2 -rich deposits (cherts) host the oldest putative evidence for life. This view is reinforced by a recent experiment that demonstrates a drastic enhancement in the appearance of prebiotic molecular components in a triphasic system adding silicates to water and reduced Miller-Urey atmosphere (Criado-Reyes et al. 2021). Due to the chemical analogies between Si and C, others have wondered about the biological essentiality of silicon for life (e.g., Exley 2009; Petkowski et al. 2020), but silicon-based life that uses Si exclusively as a scaffold element is very likely impossible (Petkowski et al. 2020). The biologically reactive Si form is its most common dissolved form, silicic acid $\text{Si}(\text{OH})_4$, which is massively present in natural waters. Most biological compartments may have been therefore visited by silicic acid since organisms rarely exclude it. This was likely the case for primitive forms of life because of the extensive Si mobilization at the surface of the early Earth caused by conspicuous Hadean-Archean seafloor-seawater hydrothermal interactions and intense Middle to Late Archean continental weathering. However, the potential role, if any, of silicon in these early biogeochemical cycles was probably complex because it certainly involved numerous Si reservoirs and processes: primary and secondary silicates, adsorption on nonsilicates, biogenic silica, and aqueous $\text{Si}(\text{OH})_4$. These multiple Si components have been shown to bear contrasted Si isotopic signatures, which may in turn potentially trace the various vectors involved in the early biogeochemical cycles. This is one way by which Si isotopes represent a timely tool in the quest for the earliest archives of life.

Silicon has three stable isotopes: ^{28}Si , ^{29}Si , and ^{30}Si with respective abundances of 92.23%, 4.67%, and 3.1%. ^{28}Si is a primary nucleus that exists owing to the nuclear oxygen-burning processes within stars whose initial compositions are hydrogen and helium rich, the two left elements from the Big Bang. Secondary nuclei ^{29}Si and ^{30}Si derive from ^{28}Si by neutron capture or by

conversion of $^{25,26}\text{Mg}$ to $^{29,30}\text{Si}$. Because they require initial carbon and oxygen in the stars, the yield of ^{29}Si and ^{30}Si production should increase with time in the universe as the interstellar gas becomes increasingly enriched in C and O. However, recent silicon isotopic measurements in space find potential gaps in such a theory because both $^{29}\text{Si}/^{28}\text{Si}$ and $^{30}\text{Si}/^{28}\text{Si}$ vary much less than predicted on the basis of O and C isotope ratio gradients across the Milky Way (Monson et al. 2017).

The Si isotopic variations in natural samples are expressed in the delta notation per mil units (‰): $\delta^x\text{Si} = 1,000 \times [({}^x\text{Si}/^{28}\text{Si})_{\text{sample}}/({}^x\text{Si}/^{28}\text{Si})_{\text{reference}} - 1]$, where x refers to the atomic mass number 29 or 30. The large Si isotopic changes (>100‰) observed in presolar grain are commonly referred to as the solar abundances (e.g., $\delta^{30}\text{Si}_{\text{Sol}}$). The Earth, Moon, and meteorite abundances, with much smaller isotopic range of variations (<14‰), are normalized relative to a quartz standard, most often the NBS28 (NIST RM8546) silica sand reference material (e.g., $\delta^{30}\text{Si}_{\text{NBS28}}$).

Si isotopes fractionate following mass-dependent laws (isotopic changes about twice larger for $\delta^{30}\text{Si}$ than for $\delta^{29}\text{Si}$) except for stellar nucleosynthesis, which is so far the sole known process by which Si isotopes are fractionated along non-mass-dependent laws. Samples whose isotopic composition derives from a mass-dependent isotopic effect will fit two near-superimposed straight lines on a three-isotope graph according to the equilibrium ($\delta^{29}\text{Si} = 0.5178 \times \delta^{30}\text{Si}$) or kinetic ($\delta^{29}\text{Si} = 0.5092 \times \delta^{30}\text{Si}$) conditions of fractionation. All solar system and terrestrial materials appear to follow these “solar-terrestrial” lines because both mechanisms cannot be distinguished within the current analytic capabilities (best present-day precision at about ± 20 –30 ppm).

Basic Methodology

Four analytic methods are available to measure Si isotopes. Two are adapted for bulk sample determination, gas source isotope ratio mass

spectrometry (IRMS), and multicollector inductively coupled plasma mass spectrometry (MC-ICP-MS, while two are dedicated for in situ micromass measurements: secondary ion mass spectrometry (SIMS) and laser ablation. Precise determinations have been gradually carried out by Si fluorination in combination with gas source IRMS (De La Rocha et al. 1996). Despite its accuracy and precision, this technique is not widely used because of its long and potentially hazardous procedures (making use of F_2 gas). The developed MC-ICP-MS methodology (e.g., Cardinal et al. 2003) is less contamination prone, quicker, and safer with similar or better precision and accuracy as shown by an interlaboratory comparison exercise ($2\sigma_M < \pm 0.15\%$, Reynolds et al. 2007). This methodology has been extended for in situ measurements using UV femtosecond laser ablation systems coupled to MC-ICP-MS (Chmieleff et al. 2008).

Key Research Findings

Significant silicon isotopic variations have been detected in ten major groups of samples, spreading different time periods, from presolar events to the modern biogeochemical Si cycle. All these isotopic fractionations were used to get new insights into the processes from which they were derived.

The major group of silicon carbide (SiC) grains preserved in the most primitive meteorites defines a non “solar-terrestrial” trend line within the three-isotope diagram, showing larger $\delta^{29}\text{Si}$ changes compared to $\delta^{30}\text{Si}$ (slope of 4/3) (Nittler et al. 2005). Their extrasolar isotopic composition suggests that they condensed outside the solar system in dense winds leaving the surface of a presolar carbon-rich asymptotic giant branch star.

Condensation stages of the solar nebula gas are recorded within the Si isotopic features of the three major components of the primitive carbonaceous meteorites: calcium-aluminum-rich inclusions (CAIs), chondrules, and matrix components. Si isotopes in high-temperature (CAIs) trace a process of partial Si evaporation-condensation at an early stage of the solar nebula

evolution. Their $\delta^{29}\text{Si}$ - $\delta^{30}\text{Si}$ plot defines a good correlation line with a mass-dependent slope of 0.5 with $-3.5\% < \delta^{30}\text{Si}_{\text{NBS28}} < +5\%$. This line includes the mean solar system composition ($\delta^{30}\text{Si}_{\text{NBS28}} = -0.5\%$) showing that the CAIs are fractionated products of the solar nebula. The lighter isotopes are preferentially lost during sublimation of the solid or evaporation from a liquid phase (Richter et al. 2009). So the CAIs enriched in heavy Si isotopes are likely residues of rapid Si evaporation while they were molten ($\sim 1\text{--}70$ days, Shahar and Young 2007). In contrast, those depleted in heavy isotopes may represent lasting-years condensates from a gas phase containing previously evaporated light Si. The much lower Si isotopic differentiations found in *chondrules* and the *matrix* components ($-1.0\% < \delta^{30}\text{Si}_{\text{NBS28}} < +0.4\%$) records the following steps of fractional condensation within the gaseous nebula (Martins et al. 2021).

The bulk meteoritic compositions were found to be homogeneous for ordinary (O) and carbonaceous (C) chondrites, at about $\delta^{30}\text{Si}_{\text{NBS28}} = -0.48 \pm 0.10\%$ (Georg et al. 2007; Savage and Moynier 2013), in good agreement with the solar wind values. In contrast, the enstatite (E) chondrites were shown to bear lighter isotopic signatures at $\delta^{30}\text{Si}_{\text{NBS28}} = -0.59\%$ and -0.77% , for low-Fe and High-Fe E-chondrites, respectively. Their lighter Si isotopic compositions are most likely due to the presence of light Si in the kamacites (Savage and Moynier 2013).

The bulk silicate Earth (BSE) composition was deduced from mantle-derived peridotitic and basaltic rocks at $\delta^{30}\text{Si}_{\text{NBS28}} = -0.29 \pm 0.08\%$ (Georg et al. 2007; Savage et al. 2010; Moynier et al. 2020). The small but resolvable difference ($\Delta^{30}\text{Si} \sim +0.2\%$) between the BSE and the O and C chondrites demonstrates that the BSE is non-chondritic with respect to Si isotopes. This is interpreted as resulting from two successive differentiation processes: (1) some light isotope Si loss by volatility during the very first stages of the Earth accretion (Moynier et al. 2020); (2) the incorporation of a significant proportion of light isotope Si (2–9 wt. %) along with metals into the Earth’s core during its segregation (Georg et al. 2007).

The strong Si oversaturation of early Earth seawater generated both Archean ► **chert** deposits and silicifications of Eo-Paleoarchean oceanic seafloors. Cherts display a very large range of Si isotopic signatures ($-2.5\text{‰} < \delta^{30}\text{Si}_{\text{NBS28}} < +2.5\text{‰}$), with an apparent secular increase in their proportion of ^{30}Si from 3.8 to 2.5 Ga. This secular change can be interpreted either as a gradual decrease of the oceanic temperature (Robert and Chaussidon 2006) or a progressive change in the Si source (Van den Boorn et al. 2010), from dominant pristine hydrothermal fluid in the early Archean ($\delta^{30}\text{Si}_{\text{NBS28}} \approx -0.3\text{‰}$) to pure seawater precipitations in the late Archean ($\delta^{30}\text{Si}_{\text{NBS28}} \gg 0\text{‰}$). Whatever the mechanism, it reflects the ^{30}Si -enriched residual character of the late Archean seawater composition consecutive to previous massive silica precipitations. In parallel this seawater-derived heavy silicon isotopic signature is massively transferred to the Archean mafic-ultramafic seafloors during their low-temperature (100–150 °C) silicifications consecutive to the seawater percolation within the oceanic seafloors (Abraham et al. 2011).

The early blocks of the continental crust (Paleo-Mesoarchean Na-rich and K-rich granitoids) display uncommon heavy Si isotopic signatures ($-0.14\text{‰} < \delta^{30}\text{Si}_{\text{NBS28}} < +0.15\text{‰}$). This requires that a notable supracrustal component in the form of seawater-derived silica had been added to their protoliths, suggesting that they formed by melting of recycled Eo-Paleoarchean silicified seafloors (André et al. 2019).

Loess samples, which are a good proxy of the bulk upper continental crust (UCC) composition, define a narrow range of Si isotopic composition ($\delta^{30}\text{Si}_{\text{NBS28}} = -0.22 \pm 0.07\text{‰}$, Savage et al. 2013), identical to average post-Archean granite and felsic rock compositions ($\delta^{30}\text{Si}_{\text{NBS28}} = -0.23 \pm 0.15\text{‰}$, Savage et al. 2012). The slightly heavier isotopic signature of the UCC ($\Delta^{30}\text{Si} \sim +0.1\text{‰}$) relative to the BSE results of two balanced processes: (1) the magnitude of isotopic fractionation ($\Delta^{30}\text{Si} \sim +0.2\text{‰}$) observed between the mafic minerals and the felsic melts during the magmatic differentiation and partial melting processes, (2) the lighter signatures

generated by the weathering processes which are transferred to the secular sedimentary mass.

Weathering conditions generate mass-dependent fractionation of Si isotopes with more negative values of $\delta^{30}\text{Si}$ in secondary soil minerals by clay desilication (Opfergelt et al. 2011) or Si adsorption onto Fe oxides (Delstanche et al. 2009) and heavier values in the percolating soil water compared to the original mineral Si source. Clays become isotopically lighter with the increase of soil weathering and clay desilication from polar to equatorial climatic zones (Bayon et al. 2018).

Siliceous organisms, such as diatoms, radiolarians, and sponges, along with amorphous silica stored in plants (phytoliths), have been well-documented as an important pool of light silicon relative to the residual heavy silicon from their ambient fresh or marine water reservoirs. Combined with clay formation and silicification, they contribute to generate the large range of Si isotopic differentiation observed in various compartments of the *modern global silicon cycle* ($-7\text{‰} < \delta^{30}\text{Si}_{\text{NBS28}} < +6\text{‰}$, Sutton et al. 2018).

The early Cambrian Explosion of Life diversity is marked by a divergence in chert $\delta^{30}\text{Si}$ which is interpreted as the consequence of the appearance of dominant forms of large silica-secreting organisms (sponges, radiolarians) which reduced oceanic dissolved Si concentrations (Ye et al. 2021). This might have removed the threat of harmful Si precipitation in organismal cytoplasm and permit energy expenditure on new metabolic functions, ultimately promoting the main stage (~ 520 Ma) of Cambrian Explosion in functional and ecological diversification (Ye et al. 2021).

Future Directions

The probability exists that a long-term record of continental weathering might be preserved in $\delta^{30}\text{Si}$ from fine-grained sediments. Considering the resistance of Si isotopes to post-emplacement metamorphic redistributions (André et al. 2006), these $\delta^{30}\text{Si}$ archives could be useful in solving the debate about the strength of soil weathering under the reducing conditions of the Archean

Eon (e.g., Delvigne et al. 2016). Better estimations of biogenic versus inorganic silica fractionation factors relative to dissolved silicic acid would also be a potential advance toward a more accurate constraint on the processes involved in the Si cycle. Significant improvements of both $\delta^{29}\text{Si}$ - $\delta^{30}\text{Si}$ analytic precision (<10 ppm) could allow to discriminate between kinetic and equilibrium isotopic fractionations. Such a progress would be essential to (1) better decipher primary and secondary processes at the origin of rock Si isotopic variations and (2) distinguish kinetically controlled biogenic Si incorporation from temperature-controlled equilibrated Si partitioning between minerals with or without fluid phases. This is another way by which Si isotopes might be a helpful tracer in exploring the rise of life.

Definition

Radio astronomers have found that the diatomic molecule SiS, containing silicon and sulfur, is quite abundant in the gas phase in the envelope expelled by the evolved star IRC + 10,216, and it has also been identified in warm gas in star-forming regions of our Galaxy. In the stellar envelope, some seven rare isotopic variants have been detected, involving ^{29}Si , ^{30}Si , ^{34}S , ^{33}S , and ^{36}S , as well as the principal isotopes ^{28}Si and ^{32}S . The abundance of SiS relative to SiO in warmer molecular clouds seems to be roughly in the ratio of the cosmic abundance of sulfur relative to oxygen.

University of Massachusetts, Amherst, MA, USA

Synonyms

[SiO](#)

Definition

This diatomic molecule is the simplest oxide of silicon. Silicon monoxide, SiO, has been detected in the gas phase in both interstellar molecular clouds and in the envelopes of evolved stars. In addition to the principal isotopic species, $^{28}\text{Si}^{16}\text{O}$, the rarer forms $^{29}\text{Si}^{16}\text{O}$ and $^{30}\text{Si}^{16}\text{O}$ are also observed. Maser emission is frequently observed from various transitions of SiO. Not surprisingly, SiO is not detected in cold, dark interstellar clouds or in the diffuse ► [interstellar medium](#), where the silicon is thought to be primarily in the ► [interstellar dust](#) grains. However, it is detected in the shocks associated to molecular outflows emanating from newly formed stars.

History

Interstellar SiO was first detected in 1974 by L. Snyder and D. Buhl at millimeter wavelengths. The maser emission from stellar envelopes is often strong enough to provide useful sources for evaluating the pointing accuracy of radio telescopes.

Definition

Simulation chambers are vessels that aim to imitate multiple environmental properties that can be found on planetary bodies in the Solar System and beyond.

Overview

Celestial bodies within, and outside, the Solar System host a wide range of environments that vary significantly to those found on Earth today. Examples of this include, the subsurface of Europa where a temperature of 0 °C and a pressure of 1500 bar exist at the seafloor-ocean interface, or on Mars where the surface temperature

and pressure are on average −63 °C and 6 mbar, respectively, and the atmosphere is dominated by carbon dioxide. In addition, with the discovery of hundreds of planets orbiting other stars, the range of environments different to Earth's is potentially limitless. Such dissimilarities in conditions makes it difficult to understand how natural processes would proceed on these worlds and how these processes can influence their evolution or assess their habitability. Simulation chambers are an invaluable resource that are commonly used in space science and exploration. They have the ability to mimic multiple physical conditions, such as pressure, gas composition, irradiation, temperature, or humidity, as well as replicating aqueous systems under controlled settings, such as lacustrine environments. In addition to scientific investigations, simulation chambers are also used to assess the performance and function of spacecraft, including landers, exploration rovers, and their instruments under environments found in open space or on other planets and satellites. A wide variety of simulation chamber have been developed and optimized for specific conditions and environments, which have either been measured by spacecraft or are expected on planetary bodies.

High pressure chambers are used to replicate the conditions identified on the surface of Venus (e.g., Lessis et al. 2019; Santos et al. 2021), and subsurface aqueous environments of bodies such as Mars and the icy moons, Enceladus or Europa (e.g., Olsson-Francis et al. 2020; Taubner et al. 2018), which are generally characterized by elevated temperatures and pressures. Such simulation chambers can use either an electric heating jacket or a fluid circulating thermal collar attached to a heater/chiller unit to maintain a constant temperature within the sample chamber (between −40 °C and +430 °C). While high pressures are achieved using either inert gases or gas mixtures, for example, a mixture of carbon dioxide, nitrogen, water vapor, carbon monoxide, and hydrogen chloride gas have been used to simulate the Venusian atmosphere (Llessis et al. 2019). Aqueous subsurface environments can be simulated either under static conditions to reflect

systems closed to incoming fluids (using the chambers described previously), or to allow the continuous flow of fluids through the reaction chamber, to reflect open aqueous systems that are commonly found in nature, such as river fed lakes or hydrothermal circulation. These open system chambers use a high-pressure pump to inject fresh fluid (from an external stock bottle) into the thermally controlled high pressure reaction chamber. An air-articulated back pressure regulator (BPR) is used to maintain a constant pressure within the chamber. As fresh fluid is added, the internal pressure of the chamber increases and causes the BPR to open and release the excess fluid, which is collected in an external effluent bottle (Fig. 1). These systems can be run under anaerobic and sterile conditions for long-term experimental runs (28 days; e.g., Ramkissoon et al. 2020), which are useful for exploring water-rock-atmosphere interactions and examining habitability.

Low pressure chambers are used to mimic the low atmospheric pressures observed on the surface of planets, such as Mars, in addition to those found on airless bodies, such as the Moon or asteroids. These types of bodies also experience variable temperatures (between -73°C and $+430^{\circ}\text{C}$) and exposure to UV radiation, which have also been incorporated into chambers to fully simulate surface conditions (Fig. 2). Chambers are evacuated using a vacuum pump to pressures between 1 and 1×10^{-10} bar, analogue atmospheric gases can be re-introduced to the chamber for low pressure environments. Sample holders are commonly cooled using liquid nitrogen to achieve temperatures as low as -180°C (e.g., Conway et al. 2011; dos Santos et al. 2016; Jensen et al. 2008; Richards et al. 2021; Sobrado et al. 2014), and heating jacket can also be applied to chambers to generate high temperature low pressure environments (e.g., Ramachandran et al. 2020). The attachment of a solar simulator or a

Simulation Chambers, Fig. 1 Schematic of a high pressure flow-through reaction chamber, which is used to simulate subsurface extra-terrestrial aqueous environments. (Source: Olsson-Francis et al. 2020))

Simulation Chambers, Fig. 2 Low pressure chamber for simulating the environmental conditions found on the surface of Mars. (Image credit: Manish Patel)

high-power UV lamp to the chamber exposes samples to high UV conditions that would be experienced on these planets, satellites, and asteroids. Other kinds of irradiation sources can also be used to simulate other stars than our Sun such as M-dwarfs (e.g., Claudi et al. 2016). In addition to allowing the exposure of different samples and taking measurements before and after, more and more chambers are also facilitate in situ monitoring of the samples via different devices (e.g., photosynthetic activity via fluorescence measurements; de Vera et al. 2014). Chambers have also been developed to simulate low pressure aqueous environments (Martin and Cockell 2015), which are similar to their high pressure counterparts. A high-performance peristaltic pump is used to feed fluid from an external stock bottle into the chamber, with excess fluid released via side arms on the chamber that connects to effluent bottles. Heater and chiller units are used to sustain a constant temperature within the chamber.

Skumanich Law

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Definition

An empirical relationship, discovered by Andrew Skumanich in 1972, between the rotation rate of a star and its age is referred to as the Skumanich Law. The equatorial speed of a star at its equator falls as the inverse square root of the star's age, for ages between 100 Myr and 10 Gyr. This law has only been established for solar-type objects, i.e., main-sequence stars of spectral type G. Along

with the rotation rate, the surface activity of such stars, such as their X-ray emission, also declines in a similar manner. This activity arises ultimately from the star's surface magnetic field. Slowing of the rotation rate occurs because solar-type stars also emit winds. Such magnetized outflows carry off angular momentum.

Slope Lineae, Recurrent

Alessandro Airo
Institut für Geologische Wissenschaften Tektonik
und Sedimentäre Geologie, Freie Universität
Berlin, Fachbereich Geowissenschaften, Berlin,
Germany

Synonyms

[Recurring slope lineae](#); [Seasonal dark flows](#);
[Warm season flows](#)

Definition

Recurring slope lineae (RSL) are seasonal dark markings on steep slopes (25–40°) that appear and progressively grow throughout the warm season and subsequently fade in the cold season (McEwen et al. 2011). RSL generally originate at rocky bedrock outcrops on slopes and are frequently associated with small channels. RSL have been found between 50 and 30°S latitude on slopes facing the equator and reaching surface temperatures during summer of up to 300 K. At these temperatures, liquid brines could develop close to the surface and percolate downhill through the subsurface pore space resulting in dark surficial “water tracks” that are known from Antarctic environments (Levy 2012). However,

the origin of these seasonal features on Mars remains debated.

Slope Streaks (Mars)

Alessandro Airo
Institut für Geologische Wissenschaften Tektonik
und Sedimentäre Geologie, Freie Universität
Berlin, Fachbereich Geowissenschaften,
Berlin, Germany

Definition

Slope streaks are dark features extending usually a few hundred meters downslope in a fan-shaped fashion and are prevalent in equatorial, high-albedo, dust-covered regions on Mars. They were first identified on images taken by the Viking Orbiters in 1977 and more than two decades later the appearance of new slope streaks was discovered (Edgett et al. 2000). New slope streaks appear to form sporadically and independent of the season (Schorghofer and King 2011). Various mechanisms of their formation have been proposed, ranging from dry dust avalanches (Sullivan et al. 2001) to wet mass wasting (Kreslavsky and Head 2009).

Small Solar System Body

Tilman Spohn
International Space Science Institute, Bern,
Switzerland

Synonyms

[Minor planet](#)

Definition

According to IAU (International Astronomical Union) resolutions five and six (Resolution GA26-5-6), all objects that are neither a satellite, a ► [planet](#), nor a ► [dwarf planet](#) are to be considered a small solar system body (SSSB). This definition covers most of the ► [asteroids](#), ► [near-Earth objects](#) (NEO), ► [comets](#), ► [trans-Neptunian objects](#) (TNO) or ► [Kuiper belt](#) objects (KBO), and other small bodies. Small bodies are bare objects without stable atmospheres. Some of the icy small bodies (in particular the comets and the distant asteroids named Centaurs) have transient atmospheres when they come sufficiently close to the Sun. The temporary atmospheres are caused by sublimation of ices heated by the solar radiation. The term “small solar system body”

SNC Meteorites

Frank Sohl¹ and Tilman Spohn²
¹DLR, Institute of Planetary Research, Berlin, Germany
²International Space Science Institute, Bern, Switzerland

Synonyms

[Martian meteorites](#)

Definition

The SNC Meteorites are a group of petrologically similar ► [Achondrites](#) named after the locations where examples of these meteorites were first found – Shergotty (India), Nakhla (Egypt), and Chassigny (France). Subgroups are the shergottites, nakhlites, and chassignites. The term SNC meteorites is sometimes restricted to the shergottites, nakhlites, and chassignites but many times includes meteorites from other findings as well. SNC meteorites are basalts, and most of them are much younger than other meteorites – with an apparent age of 1.3 Ga or younger. Together, these findings suggest that the meteorite parent body was a planetary size object. The only

undisputed example of an old SNC meteorite is ► [ALH 84001](#) – found in the Allan Hills, Antarctica, in 1984 – which is 4.1 Ga old (Bouvier et al. 2009). Most researchers accept that SNC meteorites were part of the regolith layer of ► [Mars](#), as their composition is similar to that of the Martian regolith analyzed by space probes. Gas inclusions found in some SNC meteorites resemble the Martian atmosphere in isotopic composition. It is believed that these ► [Igneous Rocks](#) probably reached escape velocity (5.4 km/s) when a body impacted Mars and thus could leave its gravity field. Later, some of these ► [Rocks](#) got captured by *Earth's* gravity field and ended up as meteorites on Earth's surface.

Snow Line

Avi M. Mandell
NASA Goddard Space Flight Center, Greenbelt,
MD, USA

Synonyms

[Frost line](#); [Ice line](#)

Definition

The snow line is the radial position within a ► [protoplanetary disk](#) where the conditions in the disk allow the existence of water ice. It implies in particular that the temperature is low enough and, equally important, that water (vapor or ice) is present in the same region. The snow line marks the transition between the inner region of the disk where water exists in the gaseous phase and the outer region of the disk where water condenses into solid ice particles. The position of the snow line changes with time and with the viscous dissipation assumed for the disk. In the ► [solar nebula](#) and other protoplanetary disks, this position is of great importance for understanding the formation and evolution of both giant and ► [terrestrial planets](#), due to the role of water as both a major constituent of the solid material in the disk and as the primary liquid medium on planetary surfaces and within planetary interiors.

Overview

The temperature structure of a protoplanetary disk is determined by both the accretion history of the disk as it forms from the stellar birth cloud and accretes onto the central star and the ongoing radiative heating from the central star itself. Viscous heating caused by accretion is mostly constrained to the midplane of the disk, so the radial temperature structure is primarily driven by heating from the central star and decreases from the inner disk to the outer disk. The inner regions of the disk can be heated by the central star to more than 5,000 K, while the outer regions of the disk beyond 50 AU can have gas and grain temperatures as low as 10 K, based on studies of comets in our own Solar System.

This substantial range in temperature encompasses the sublimation temperatures for many chemical species within the protoplanetary disk, leading to “condensation fronts” where a specific chemical constituent transitions from the gaseous phase to the solid phase. Refractory materials such as silicates have very high condensation temperatures and condense out in the inner disk, while volatile materials such as water and methane

condense out at larger distances from the central star. The condensation temperature for water in a low-pressure environment such as a protoplanetary disk is ~ 150 K; early models of the minimum-mass solar nebula suggested that this transition temperature would occur at 2.7 AU in our own Solar System, but since then the location and evolution of the snow line has been a topic of debate (see below).

The location of the snow line during the formation of planets in a circumstellar disk is important for several reasons. First, H_2O is thought to comprise at least half of the available solid material in a protoplanetary disk, based on thermochemical models of the solar nebula. Therefore, the density of solid material beyond the snow line will be much greater than the density of solid material within the snow line, leading to faster growth of planets and larger planetary cores beyond the snow line. This enhancement has been invoked to explain the fact that all the giant planets in our Solar System orbit beyond 5 AU – the larger planetary cores beyond the snow line were able to reach the critical mass for runaway gas accretion, while smaller planetary cores within the snow line never accreted significant gaseous atmospheres.

The location of the snow line is also important for constraining the source and abundance of water on the terrestrial planets, particularly Earth. If all the source material for the terrestrial planets formed within the snow line where the water content of planetesimals would be very low, there should be very little water on the surfaces or in the interiors of planets in the inner system. We clearly know of only one planet with a significant water fraction today (Earth), the Moon is essentially dry, and there may have been significant amounts of water on both Venus and Mars at the time of their formation; the origin of the water on Earth and the potential for water-rich terrestrial planets in other planetary systems are therefore an active area of research (see below).

Key Research Findings

The location of the snow line during the formation of the Solar System, and by extension other

planetary systems, is an area of active research. Hayashi (1981) first calculated the location of the snow line in the minimum-mass solar nebula to be at 2.7 AU; however, the calculation was only an energy balance between the solar radiation absorbed and re-emitted from a ► [blackbody](#) absorber. Since then our knowledge of the various heating and cooling processes in the solar nebula has advanced significantly, improving our ability to determine the temperature structure of the disk over time. Calculations by Sasselov and Lecar (2000) and Lecar et al. (2006) incorporated more recent models of protoplanetary disk structure and included heating from accretion and solar radiation and variations in condensation temperature with gas density. They found that for a minimum-mass solar nebula with low levels of accretion similar to observed protoplanetary disks, the snow line would lie between 1.6 and 1.8 AU; however, increasing the mass, the accretion rate, or the opacity of grains in the disk could move the snow line out as far as 3.5 AU.

The role of the snow line in aiding the formation of giant planets is also still under debate. The obvious increase in planet mass beyond 5 AU naturally correlates with the enhancement of solid material beyond the snow line, but this increased mass has been thought to be insufficient to overcome the long dynamical timescales for accretion in the outer Solar System; estimated timescales for unaided core accretion in the giant planet region were 10^7 – 10^8 years, much longer than the lifetime of gas in the solar nebula. Beginning with Stevenson and Lunine (1988), who postulated that water vapor in the disk would be redistributed to the snow line by eddy diffusion and lead to core formation at the condensation front, various researchers have invoked processes that could lead to a buildup of material at or near the snow line and lead to rapid core formation. Recent hydrodynamic simulations of giant ► [planet formation](#) with a more accurate treatment of the role of the expanding planetary atmosphere seem to suggest that no additional mechanism is necessary (Lissauer et al. 2009), but this does not rule out other enhancement processes.

The other active area of research relating to the snow line concerns the delivery of water

and other volatile material to the terrestrial planets. If the snow line was located beyond the orbit of Mars, as would be expected based on models and the water content of asteroids in the asteroid belt, then the bulk of the material that formed the terrestrial planets should have been very water poor. However, we know that the Earth has a water mass fraction of $\sim 0.1\%$, and there is evidence of significant past water flow on the surface of Mars over geologic time-scales. Researchers have debated whether the Earth's water was delivered primarily by comets from the Jupiter-Saturn region (e.g., Delsemme 2000) or by hydrated asteroids from the outer asteroid belt (e.g., Morbidelli et al. 2000), relying primarily on comparisons between the deuterium-to-hydrogen ratio (D/H) for Earth's water and that of different classes of Solar System bodies. More recent simulations of the final stages of the accretion of terrestrial planets have shown that water-rich asteroid-type planetesimals from 2 to 3 AU are naturally incorporated into terrestrial planets during the late stages of formation (Raymond et al. 2007; Bond et al. 2010).

Snowball Earth

Paul Felix Hoffman

School of Earth & Ocean Sciences, University of Victoria, Victoria, BC, Canada

Department of Earth & Planetary Sciences, Harvard University, Cambridge, MA, USA

Keywords

Albedo · Atmospheric oxygenation · CO₂ hysteresis · Energy balance models · Fe-Mn ore deposits · Greenhouse effect · Ice grounding line · Ice sheet · Paleomagnetism · Radiative forcing · Geochemical carbon cycle · Silicate-weathering feedback · Volcanic-metamorphic outgassing · Multicellular animals

Synonyms

[Hard snowball](#); [Ice-albedo bifurcation](#); [Large ice-cap instability](#); [Panglacial](#)

Definition

Planets with surface oceans are vulnerable to run-away glaciation due to a bifurcation in ice-line latitude caused by ice-albedo feedback. In the stable panglacial state, the oceans are covered everywhere by equatorward-flowing ice shelves

(sea glaciers) and continents are partially covered by slow-moving ice sheets fed by sublimation off the equatorial sea glacier. If such a planet is tectonically active, feedback in the geochemical carbon cycle may allow volcanogenic atmospheric CO_2 to slowly accumulate, in the absence of rainfall, to the point where greenhouse radiative forcing overcomes the high planetary albedo, leading to rapid total deglaciation and a transient hyperthermal aftermath, in which high CO_2 coexists with low surface albedo. Snowball Earth (Kirschvink 1992; Hoffman et al. 2017) postulates that the scenario just described occurred on Earth (Fig. 1), twice in rapid succession less than a billion years ago – 717–661 Ma (Sturtian) and 645(±5)–635 Ma (Marinoan) – and ~2.43 billion years ago (Makganyene), based on more fragmentary evidence.

History

The globally widespread occurrence of “Eo-Cambrian” glacial deposits (Fig. 2) was first

recognized by Swedish geologist Oskar Kulling (1934), and their stratigraphic association in certain areas with nonskeletal marine carbonate rocks (Fig. 2b, d), which form preferentially in the warmest parts of the surface ocean. The ice-albedo bifurcation (Fig. 3a–b) was revealed at the end of 1960s by physical climatologists. The panglacial state was initially assumed to be irreversible and therefore not geologically relevant. This changed when planetologists Walker et al. (1981) pointed out that a panglacial state on Earth would likely be self-reversing due to negative feedback in the geochemical carbon cycle (Fig. 3c–d). American paleomagnetist J.L. Kirschvink (1992) was the first to apply the concept of a self-reversing ice-albedo bifurcation to the geologic record, inspired by paleomagnetic evidence of low paleolatitude for Marinoan tidewater glacial deposits in South Australia. Kirschvink (1992) coined the term Snowball Earth, alluding to its appearance from space, and posited three occurrences in the geologic record (Fig. 1): Marinoan, Sturtian and Makganyene (Kirschvink et al. 2000); each being represented by non-Alpine

Snowball Earth, Fig. 1 Climate states on Earth since 3.0 Ga, the limit of the quasi-continuous sedimentary record (Hoffman et al. 2017). Three equilibrium states are (1) Snowball Earth (see Definition in the text), (2) regional high-latitude ice sheets, ice shelves, and sea ice, (3) absent non-alpine glaciers and ice sheets. (a) 740–620 Ma (10^6 year before present). Black bands indicate radiometrically determined durations of Sturtian and Marinoan Snowball Earths (Rooney et al. 2015; Zhou et al. 2019). Graded start to Marinoan denotes chronometric uncertainty, not gradual onset. Ellipse F–LIP (Franklin Large Igneous Province, NW Canada) shows possible age span of flood-basalt volcanism on the paleo-equator, coincident with Sturtian onset

(Macdonald et al. 2010, 2018) and postulated as a climate-change driver (Cox et al. 2016b; Macdonald and Woodward 2017). (b) Climate states on Earth since 3.0 Ga: Snowball Earths (black), regional ice sheets (medium grey), no ice sheets (light grey). Ellipse GOE is centered on the Great Oxidation Event, as recorded by the disappearance of mass-independent S isotope fractionations ≥ 0.3 per mil in non-detrital sedimentary sulfide and sulfate minerals (Farquhar and Wing 2003). Dashed gray line at 1.8 Ga indicates possible glaciation (Williams 2005) within a 1.5-Gyr non-glacial interval. (Modified after Hoffman et al. 2017)

Snowball Earth, Fig. 2 The sedimentary record of Snowball Earth. (a) Evidence of dynamic glacial action: classic exposure described and interpreted by Reusch (1891) as a glacial moraine (upper left), deposited on a subglacial bedrock (quartzite) pavement on which two intersecting sets of striations (arrows) indicate successive ice flow directions at Bigganjar'ga, Varanger Peninsula, Finnmark, North Norway. View looking eastward with 0.33-m-long hammer (circled) for scale. The glacial features here were later shown to be Marinoan in age (Edwards 1984; Rice et al. 2012) and indicate that net snow accumulation was sufficient to generate glaciers that flowed by meltwater-lubricated basal sliding. Sturtian and Marinoan glaciation was recognized early on in the North Atlantic region, where geologists were familiar with Quaternary and active glaciers and glacial products. (b) Evidence of glacial action in tropical seas. Marinoan carbonate turbidites and debrite with an ice-rafted dropstone (center) composed of oolitic limestone that depressed the underlying layers upon impact, ejected the doubly-folded layer (below 2-cm-diameter coin) at the surface when impact occurred, and was subsequently draped and buried by post-impact layers (under coin). These subaqueous deposits are composed of glacially-eroded carbonate detritus that accumulated near the grounding line of a floating ice shelf (Domack and Hoffman 2011), which melted basally releasing trillions of dropstones. The oolitic limestone was eroded from a falling-stand carbonate wedge formed during sea-level fall due to ice buildup at higher latitudes during the Marinoan glacial inception. Ghaub Formation (Otavi Group) on the foreslope of a long-lived

marine carbonate platform, near Fransfontein, Kunene Region, Namibia. In this area, both Sturtian and Marinoan glacial deposits occur within a thick shallow-water carbonate succession that accumulated in a relatively warm part of the ancient surface ocean. If the warmest areas were glaciated, colder regions must have been frozen as well. (c) Sturtian cap carbonate in Zavkhan terrane west of Taishir, western Mongolia (Bold et al. 2016; Rooney et al. 2015). Orange-weathering stratified glacial marine deposits (Maikhan Uul Formation) with ice-rafted debris (arrow) are sharply overlain without evident hiatus by dark gray, organic-rich, fossiliferous limestone (basal Taishir Formation). Abrupt onset of carbonate sedimentation is typical of Sturtian and Marinoan glacial terminations. Geologist at right for scale. (d) Marinoan cap carbonate in Namibia (Hoffman 2011). Drape of stratified carbonate debris with ice(berg?)-rafted dropstones (Ghaub Formation, Bethanis Member), recording terminal deglaciation, is sharply overlain without evident hiatus by pale pinkish to buff colored micropeloidal dolostone (Keilberg Member of Maieberg Formation). Note abrupt termination of carbonate debris at the base of the cap dolostone (by geologist's left hand). The cap dolostone extends far beyond the area of glacial deposits, which are mainly localized on the narrow foreslope of a vast ($>2.10^8$ m²) glacially-eroded marine carbonate platform. Average depth of Marinoan glacial erosion was <10 m. Cap carbonates are products of slow snowball ocean acidification and buffering, followed by rapid ocean warming, shelf flooding, loess weathering, and deacidification. (Images taken by author PF Hoffman)

Snowball Earth, Fig. 3 Generic bifurcation diagram illustrating the Snowball Earth hysteresis loop (Hoffman et al. 2017). Ice-line latitude as a function of solar or equivalent CO_2 radiative forcing in one-dimensional (meridional) energy-balance models (Budyko 1969; Sellers 1969; North et al. 1981). Three stable branches (red, green, and blue) are separated by an unstable regime (dashed). Yellow dots are stable climates possible with present-day forcing. Black arrows indicate non-equilibrium transitions. In response to lower forcing, ice line migrates equatorward to the ice-albedo instability threshold (a), whereupon the ice line advances uncontrollably to the equator (b). With reduced sinks for carbon, normal volcanic outgassing drives atmospheric CO_2 higher over millions to tens of millions of years (Le Hir et al. 2008b) until it reaches the deglaciation threshold (c). Once the tropical ocean begins to open, ice-albedo feedback drives the ice line rapidly poleward to (d), where high radiative forcing combined with low surface albedo creates a transient hyperthermal climate with global mean sea-surface temperature ~ 323 K (Yang et al. 2017). Intense silicate weathering and organic burial lower atmospheric CO_2 in $\sim 10^7$ years (Mills et al. 2011) to (e) the threshold for reestablishment of a polar ice cap. The hysteresis loop (a→f) predicts that Snowball Earth epochs were long-lived (b→c), began synchronously at low latitudes (a→b), and ended synchronously at all latitudes (c→d) under extreme CO_2 radiative forcing. The ocean is predicted to undergo severe acidification and deacidification in response to the CO_2 hysteresis (Higgins and Schrag 2003; Le Hir et al. 2008b). Qualitatively similar hysteresis is found in three-dimensional general circulation models. $p\text{CO}_2$, partial pressure of CO_2 ; wrt, with respect to. (Modified after Hoffman et al. 2017)

glacial deposits formed at low paleomagnetic latitudes. Geologists broadly accepted the snowball Earth concept after radiometric geochronology established that the postulated glaciations were long-lived and globally synchronous (Rooney et al. 2015; Zhou et al. 2019).

Basic Methodology

Since postulated climatic boundary conditions during a Snowball Earth and its hyperthermal aftermath lie far outside geologic norms, improved theory is needed to properly ascertain the predicted consequences, and intelligently investigate the geologic record (Pierrehumbert et al. 2011; Hoffman et al. 2017). The basic bifurcation has been investigated in coupled atmosphere–ocean–sea ice general circulation models (see Abbot et al. 2013; Hoffman et al. 2017), as have the viabilities of low-latitude marine ice margins (Rose 2015). The low temperature and solid surface of the panglacial state dictate a shallow troposphere and vigorous Hadley circulation above a surface with little thermal inertia (Pierrehumbert 2005; Voigt and Abbot 2012; Voigt 2013). The result is a weak hydrologic cycle in which net equatorial sublimation in the annual mean drives net meteoric accumulation elsewhere (Fig. 4), principally in the subequatorial zones (Abbot et al. 2013). Thus, the water balance between the equatorial and subtropical zones is reversed, relative to any climate state with liquid surface water. Tropical surface winds are strong, but boundary-layer inversions, due to surface heat loss by radiation, decouple the winds from the surface in the winter hemisphere (Pierrehumbert 2005; Pierrehumbert et al. 2011). Atmospheric aerosols and clouds have net warming effects that make deglaciation possible and may dictate its timing once CO_2 levels are high (Abbot 2014). After the tropical ocean becomes ice covered at a panglacial onset, marine ice thickens to roughly 10^3 m within a few 10^4 years (Fig. 5a), with as little as 10% difference between polar and equatorial ice thickness, due to sea-glacier flow (Tziperman et al. 2012). Thin ice is generally precluded by glacial inflow, but may occur in constricted seaways and silled basins where situated in the equatorial zone of net ablation. The sea glacier becomes thinner in response to CO_2 rise, but the change may be smallest at the equator if thickness gradients flatten as the ice warms and softens (Tziperman et al. 2012; Abbot et al. 2013). Continental ice sheets thicken more slowly after panglacial onset, depending on topography, but

Snowball Earth, Fig. 4 Zonal mean precipitation minus evaporation/sublimation as a function of latitude on present Earth (blue dashed), an aquaplanet (blue solid) under the same boundary conditions, and Snowball Earth (magenta) with 94% Solar luminosity and 0.1 (dashed) or

100 (solid) mbar CO₂ (generalized from Abbot et al. 2013). Note equatorial desert in Snowball Earth, with subtropical maxima in net precipitation and absence of polar deserts. Note scale difference for Snowball Earth. (Original figure by author PF Hoffman)

Snowball Earth, Fig. 5 The cryosphere on Snowball Earth. (a) Sea glacier steady-state thickness and flow lines in a prescribed Snowball aquaplanet that is relatively warm (i.e., high CO₂) and has a spatially uniform surface dust flux of 1 m Myr⁻¹ and uniform ice albedo (Li and Pierrehumbert 2011, Goodman and Pierrehumbert 2003). The sea glacier consists of meteoric ice (compressed snow) and marine ice (frozen seawater): exposure of lower-albedo marine ice causes warming and thinner ice. Adjusting surface albedo for dust accumulation results in thinner ablation-zone ice (Fig. 7b) and non-steady state pulses of

equatorial sea-glacier invasion (Goodman and Strom 2013). (b) Changes in ice-sheet mass balance in response to variable CO₂ radiative forcing in an ice-sheet-atmosphere general circulation model with Marinoan paleogeography and a totally ice covered ocean (Benn et al. 2015). Note the increase in ice-free land area as CO₂ rises, and its concentration in areas where intense Hadley cells generate strong seasonal surface winds and dust plumes (Voigt 2013; Pierrehumbert et al. 2011). (Modified after Hoffman et al. 2017)

reach dynamic steady state within a few 10^5 years (see Benn et al. 2015). This implies that glacial erosion and sedimentation were ongoing through 99% and 96% of the Sturtian and Marinoan epochs, respectively. Net sea-level falls of $\sim 5 \cdot 10^2$ m occur on most continental margins, despite the countervailing effects of ice gravity and isostatic adjustments (Benn et al. 2015, among others). As CO_2 rises, ice-sheet mass balance becomes sensitive to orbital forcing, causing ice-margin migrations of $\leq 5 \cdot 10^5$ m on a precessional ($2 \cdot 10^4$ year) time scale (Benn et al. 2015). Although ice sheets flow faster as CO_2 rises, their area and mass contract (Fig. 5b), leaving increasingly large fractions of tropical land area free of glacial ice (Benn et al. 2015). The only heat received by the subglacial ocean is geothermal: heat is lost at the top by diffusion through the ice cover (Jansen 2016). The Snowball ocean is consequently well mixed by eddies and is nearly isothermal and isohaline (Ferreira et al. 2011; Ashkenazy and Tziperman 2016; Jansen 2016). It is weakly stratified because isopycnal surfaces incline toward the poles, where heat dissipation is greatest through the nearly uniform-thickness ice shell (Jansen 2016). Tidal mixing is also strong in the absence of dissipation on continental shelves, which are ice covered or emergent. Zonal jets occur close to the equator at shallow depths beneath the sea glacier, and pulsating cavities of thinner ice develop on basin margins where such jets are directed offshore (Ashkenazy and Tziperman 2016). Whereas atmospheric dynamics on Snowball Earth have parallels with Mars, ocean dynamics have much in common with the Arctic Ocean. The role of seafloor weathering in CO_2 consumption on Snowball Earth, was investigated by Le Hir et al. (Le Hir et al. 2008a, b). Since basalt weathering rates are pH dependent at low temperature, seafloor weathering should not prevent early CO_2 rise on a Snowball Earth, but it could delay final deglaciation by limiting CO_2 rise (Le Hir et al. 2008b).

Key Research Findings

A key advance has been the development of a radiometric chronology (Fig. 1 and first paragraph) for Sturtian and Marinoan glaciation

(Rooney et al. 2015; Prave et al. 2016; Zhou et al. 2019). Strong predictions of the Snowball scenario – prolonged (106–108 year) glaciation at low latitude (Fig. 3b–c) and synchronous deglaciation globally (Fig. 3c–d) – are supported for both (Rooney et al. 2015). The chronology permits comparison of their average sediment accumulation rates with younger high-latitude glaciations of comparable duration. Sturtian and Marinoan accumulation rates were 3–10 times slower, reflecting the weak hydrologic cycle and slow-moving ice sheets on Snowball Earth. Sturtian and Marinoan deglaciations are uniquely associated with globally extensive carbonate deposits called “cap carbonates” (Fig. 2c, d) having unusual sedimentological and geochemical attributes (Hoffman and Schrag 2002; Shields 2005; Hoffman et al. 2017). Severe ocean warming, meltwater production, terrestrial and seafloor weathering, shelf flooding and vertical mixing are all implicated in their origin and alteration (Shields 2005; Yang et al. 2017; Ahm et al., 2019). Sturtian and Marinoan cap carbonates are quite distinct. The latter contain barite (BaSO_4) of sea-floor and shallow-subsurface origin, in which sulfate-oxygen isotope anomalies produced by photochemical reactions in the stratosphere record extreme atmospheric CO_2 relative to (non-negligible) O_2 concentrations (Cao and Bao 2013) and rapid global deglaciation. Many workers assume that slow acidification of the subglacial ocean was buffered by dissolution of detrital carbonate delivered by tropical glaciers (Higgins and Schrag 2003; Le Hir et al. 2008a, b), but rapid ocean acidification upon deglaciation has been inferred from boron-isotope pH proxy data. Expanded meridional extent of cap carbonate and profuse crystallization of benthic aragonite (orthorhombic CaCO_3) at thermocline depths indicate anomalous carbonate oversaturation during Marinoan deglaciation. A comprehensive theory for cap carbonates is the supreme challenge and ultimate reward of the Snowball Earth hypothesis. Numerous occurrences of sedimentary iron formation imply that Sturtian oceans were anoxic and ferruginous (Kirschvink 1992; Cox et al. 2016a). Their co-occurrence with ice grounding-line deposits implicates subglacial meltwater discharge as an

oxidant source. The more ancient Makganyene event involved non-Alpine glaciation at low ($11\pm4^\circ$) paleolatitude around 2.43 Ga in South Africa, but the duration and extent of this glaciation remain to be determined. Multiple glaciations occurred between 2.2 and 2.5 Ga on different paleocontinents, but existing radiometric constraints do not require strict contemporaneity. The Makganyene glaciation appears to stratigraphically predate the Great Oxidation Event, contrary to suggestions that glaciation was caused by oxidative collapse of a methane-supported greenhouse, but potentially consistent with Snowball-induced oxygenation. Extreme isotopic depletions in oxygen and hydrogen, widely observed in 2.2–2.5-Ga crustal rocks in Arctic Europe, which then arguably lay in low latitudes, could be a record of subglacial recharge of groundwater on a Snowball Earth (Bindeman and Lee 2018). Existing chronology suggests that depleted groundwater existed in Arctic Europe around Makganyene time and again ~ 2.29 Ga (Zakharov et al. 2017), potentially correlative with the younger Rietfontein glaciation in South Africa.

Ongoing Research: Biological Consequences

The biological consequences of any given Snowball Earth are not predictable from existing evolutionary theory. The physical microfossil record indicates a prolonged (10^8 year) minimum in within-assemblage diversity and age-scaled species richness that began $\leq 2.10^7$ year before Sturtian onset and ended $\leq 3.10^6$ year after Marinoan termination. The emerging molecular biomarker record from indigenous sediment-hosted bitumens and oils is revelatory (Fig. 6). A revolution in marine primary production occurred, not in the immediate Sturtian aftermath but within the 10–15 Myr nonglacial interlude before the Marinoan. It is recorded by a stepwise increase in sterane/hopane ratio (Fig. 6e) (i.e., algal versus bacterial production), in abrupt first appearances of stigmastane (C_{29}) and ergostane (C_{28}) as predominant steranes (Fig. 6c), and isopropyl- and n-propyl-cholestane (C_{30}) in trace amounts (Fig. 6d) (Brocks 2018; Gold 2018, among others). The major steranes record the ascendance of green algae as major marine primary producers, an hegemony among eukaryotes

they would retain until the Mesozoic rise of secondary endosymbiotic (chlorophyll *c*) algae (Brocks 2018; Gold 2018). Despite the exclusion of phototrophism beneath a sea glacier, supraglacial meltwater-associated cyanobacterial mats, made possible by surface-darkening dust (cryoconite), would have created oligotrophic ecosystems on Snowball Earth in which select eukaryotic (green) algae, fungi, protists and possibly even metazoans survived, grew and evolved (Vincent et al. 2004). Such freshwater ecosystems would have greatly expanded in response to Snowball Earth. Strong surface winds (Pierrehumbert 2005; Voigt and Abbot 2012) and orbitally-driven waxing and waning of ice sheets (Benn et al. 2015) ensured ample supplies of dust, which sea-glacier flow would have delivered to the ablative ice surface (Fig. 5a), creating an equatorial zone dotted by cryoconite holes, ponds and streams over $\sim 12\%$ of global surface area (Hoffman 2016). In addition, glacier-free land areas would have held ice-covered meromictic (salt-stratified) brine lakes, where oligotrophic phototrophs including benthic mat-forming cyanobacteria and planktonic picocyanobacteria (*Synechococcus*) now preside in polar deserts (Sumner et al. 2016). It is perhaps not surprising, therefore, that relaxed molecular clock analysis suggests that major groups of modern marine cyanobacteria, including nitrogen-fixers and the syn-pro clade of planktonic picocyanobacteria, which dominate the oligotrophic subtropical gyres of modern oceans and account for $\sim 5\%$ of total organic productivity (Zehr et al. 2017), have last common ancestors of roughly Sturtian–Marinoan age (Sanchez-Baracaldo 2015). Moreover, trait evolution analysis suggests that they stemmed from freshwater lineages (Sanchez-Baracaldo 2015). Nitrogen isotope fractionations in Marinoan glacial marine sediments indicate active nitrogen cycling, suggesting that cyanobacterial nitrogen cycling in modern polar and alpine environments (Fernandez-Valiente et al. 2001; Cameron et al. 2012) might not be a recent adaptation. More intriguingly, certain cyanobacterial clades appear on molecular phylogenetic grounds to have cold-tolerant basal groups and derived groups in other environments, the cosmopolitan genus *Nodularia* being a potential example (Christmas et al. 2015).

Snowball Earth, Fig. 6 Time chart for 850 Ma to present environmental, biomarker, and fossil data highlighting the position of the rise of algae (figure and caption from Brocks et al. 2017; data sources referenced therein). Note the condensed time scale after 541 Ma. (a) Speculative trajectory of atmospheric O_2 (turquoise) and P concentrations in shales before (red) and after (green) the rise of algae (dashed red line). (b) Marine carbonate C isotopes in permil relative to Vienna Pee Dee Belemnite. (c) Relative abundances of steranes: cholestane (red), ergostane (blue), and stigmastane (green) in 20-Myr-time bins. Red circles indicate average cholestane abundances and blue triangles denote isolated occurrences of ergosteroids before the algal rise, based on data from ten formations in Oman, Australia, USA, and Sweden. No reliable sterane record exists before 800 Ma. Note algal gap in each Snowball aftermath. (d) Occurrence of unusual steranes (see h for structures; dashed lines indicate absence). Cryostane (26-methylcholestane) is restricted to pre-Sturtian time and its biological source is unknown, but the only extant organisms that have the biosynthetic capacity to methylate sterol in the 26-position are demosponges (Brocks et al. 2015). 24-ipc is regarded as a biomarker for demosponges (Love et al. 2009; Gold et al. 2016 [but see Bobrovskiy et al.

2020]). It emerges after the Sturtian aftermath but before Marinoan onset (Love et al. 2009) and remains abundant throughout the Ediacaran (635–541 Ma). 24-npc also emerges before Marinoan onset, revealing the activity of rhizaria (a group that includes foraminifera and radiolarians). (e) The relative contribution of eukaryotic (Euk) and bacterial (Bact) lipids to sedimentary organic matter approximated by the sterane/hopane ratio (Ster/Hop) before (red) and after (green) the rise of algae. (f) Succession of dominant primary producers (PP) in the oceans: bacterial phototrophs were dominant before the rise of primary endosymbiotic algae (Archaeplastida), heralded by sharply increasing sterane/hopane ratios and the emergence of abundant ergostane and stigmastane. Archaeplastids were replaced as the dominant algae after the Permo–Triassic mass extinction by secondary endosymbiotic (chlorophyll c) algae as recorded by rising ergostane/stigmastane ratios. (g) First occurrences of eukaryotic groups in the fossil record, Blue line is the mean within assemblage diversity (WAD) of unique eukaryotic species or morphotypes per stratigraphic unit (Cohen and Macdonald 2015). (h) Color-coded sterane structures. (From Brocks et al. 2017)

Snowball Earth, Fig. 7 Supraglacial meltwater ecosystems on Snowball Earth (modified after Hoffman 2016). (a) Global paleogeography during the Sturtian Snowball Earth at 680 Ma. Continental ice sheets outlined. Reddish areas schematically indicate dry-valley dust sources (Abbot and Halevy 2010; Benn et al. 2015) and brownish areas indicate the sea-glacier ablation zone where glacially-advected dust accumulates as cryoconite (Abbot and Pierrehumbert 2010; Li and Pierrehumbert 2011; Goodman and Strom 2013), creating oligotrophic meltwater-associated ecosystems capable of supporting cold-tolerant cyanobacteria, green algae, fungi, unicellular heterotrophs, and even certain metazoans (Vincent et al. 2000, 2004; Christner et al. 2003; Hawes et al. 2018). (b) Snapshot of a two-dimensional ice flow model of Snowball Earth with a global dust accumulation rate of 10 m Myr^{-1} (Goodman and Strom 2013). Dark cryoconite (mineral dust suffused with deeply-pigmented extracellular polymeric substances copiously secreted by cyanobacteria) and exposed low-albedo marine ice make the sublimative

ice warm and thin. Hemispheric asymmetry at low latitudes reflects unsteady, quasi-periodic, reciprocal ice surges from the respective subtropics in the model (Goodman and Strom 2013). Flushing of meltwater through moulins is shown schematically. The apparent ice walls at 18° latitude have actual slopes of 1 m km^{-1} . Organic production and aerobic respiration are nearly balanced within cryoconite holes and pans. Flushed cryoconite organic matter (typically 10 wt%) is subject to anaerobic respiration in the water and sediment columns. Fe(III) and sulfate are sourced from the flushed cryoconite and oxidative sub-ice sheet weathering. Assuming coldwater anaerobic respiration is incomplete, organic matter is buried, and O_2 is added to the atmosphere, as is required to offset O_2 consumption by volcanic SO_2 and H_2S emissions and sea-floor weathering (Hoffman 2016). Redox proxy evidence supports transient oxygenation in the Sturtian aftermath (Pogge von Strandmann et al. 2015; Lau et al. 2017). (Modified after Hoffman et al. 2017)

Future Directions

An outstanding question concerns the grossly unequal durations of the Sturtian and Marinoan Snowballs, 58 and 5–15 Myr respectively (Fig. 1). Is this difference related in any way to their contrasting geochemical attributes – syn-glacial sedimentary iron-formations are (nearly?) all Sturtian, whereas barite and seafloor aragonite occur in cap carbonates only of Marinoan age (Hoffman et al. 2011)? The brief nonglacial interlude, 15 ± 5 Myr, is in the estimated range for post-Sturtian CO₂ drawdown. Was Marinoan onset simply the return to ambient conditions at Sturtian onset, 72 ± 5 Myr earlier? If so, why was post-Marinoan glaciation delayed for 55 Myr? How close did we come to a Carboniferous Snowball Earth (Feulner 2017), and how might that have changed the history of life? Also unresolved are the causal factors for each Snowball Earth inception. Paleogeographic factors like supercontinent breakup could cool the climate through enhanced weathering and organic burial (Donnadieu et al. 2004), but while Sturtian–Marinoan glaciation did accompany such a breakup (Zhang et al. 2013), supercontinents broke up at other times without severe glacial response. Contemporaneity of Sturtian onset (Fig. 1) with equatorial flood-basalt emplacement supports enhanced silicate weathering (Cox et al. 2016b; Godderis et al. 2003) and stratospheric aerosol injection (Macdonald and Wordsworth 2017) as potential factors, but the Marinoan and Makganyene are not known to have had volcanic outbursts at their inceptions. Biological innovations have been advanced as causal factors also (e.g., Feulner et al. 2015; Isson and Planavsky 2018), but correlation with unique events is frustratingly not subject to induction in nature.

Social Study of Science

Klara Anna Capova
Department of Anthropology, Durham University,
Durham, UK

Acronyms

STS Science and Technology Studies, also
Science, Technology and Society

Synonyms

[Anthropology of science](#); [Science and society studies](#); [Science studies](#); [Social studies of science and technology](#); [Sociology of science](#)

Definition

Social study of science, or science and technology studies (STS), also anthropology of science and technology, is an interdisciplinary field of social sciences concerned with the roles of sciences and technologies in society, conditions and context under which scientific knowledge and technological advancements are produced, and with social changes and societal impacts they make.

Overview

The social studies of science and technology developed from the tradition of sociology, history, and philosophy of science (i. e., Russell 1951; Kuhn 1962). Taking sciences and technologies as objects of a critical study, these new fields of social research approached sciences as historically, socially, politically, and culturally situated local practices rather than uniform, universal, and value-neutral processes of knowledge production (Jasanoff 1995; Martin 1998). The ethnographic and historical studies of science provide accounts of the works of scientific communities and social context of inventions (e.g., Latour 1987; Traweek 1988; Rabinow 1996), showing how science is socially embedded and positioned in the configuration of scientific, technological, cultural, social, economic, political, and legal elements.

As a newly formed interdisciplinary and multi-disciplinary field of scientific practice and knowledge production, astrobiology as a science presents new directions for the social study of science. Namely, the epistemological issue emerges regarding its disciplinary boundaries and the very status of astrobiology as a science. Astrobiology has contemporary societal implications and relates to topics of a cultural, ethical, educational, political, and legal importance. Those include societal reaction to the discovery of extraterrestrial life; role of astrobiology in primary, secondary, and tertiary education; science dissemination and outreach; commercial and industrial use of outer space; moral and legal

status of extraterrestrial life; environmental ethics in space, technological innovations, and commerce among other.

[Contribution of science to society](#); [Socioeconomic impact](#); [Value](#)

Acronyms

UN	United Nations
SDG	Sustainable Development Goals
UNOOSA	United Nations' Office for Outer Space Affairs

Overview

Since the Apollo program, space exploration has been recognized as a world-view shifting activity with undeniable inspirational and aspirational aspects and an accelerator of technological development and scientific advancements. The idea that the knowledge, technologies, and know-how developed to explore space can make life on Earth more productive, clean, and sustainable is becoming more prominent and articulated in numerous initiatives and policies. The United Nations' Sustainable Development Goals (UN SDGs) agenda was adopted by all UN Member States in 2015 as a universal call to action to end poverty, protect the planet, and ensure that all people enjoy peace and prosperity by 2030. The 17 interlinked goals define global social, environmental, and economic sustainable development priorities (planet, people, prosperity, peace, and partnership) and are often referred to as existential importance for humanity.

Space has been recognized as a driver for sustainable development by the UN Office for Outer Space Affairs (UNOOSA) that as such promotes the utilization of space science and technology for sustainable economic and social development. According to UNOOSA (2018), space technologies in general have an impact on almost all aspects of development: agriculture, global health, environment, education, research and development, human settlements, transportation, communication, humanitarian assistance, and security.

In relation to astrobiology, the broader societal benefits of the Martian missions rest in its immense inspirational, cultural, educational, and science dissemination potential and ability to engage wide audiences globally (Capova et al. 2018). Technologies developed for astrobiological research on Mars may have unique potential to leverage innovative solutions and

further contribute to sustainable socioeconomic development on Earth in the near future (e.g., robotics, energy solutions, and sample analysis).

Soda Lake

Daniele L. Pinti
GEOTOP, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montreal, QC, Canada

Keywords

Alkaline environments · Extreme environments · Natron · Rift Valley lakes · Thermonatrite

Synonyms

[Alkaline lake](#); [Carbonate lake](#); [Hypersaline lake](#)

Definition

Soda lakes are lakes with pH up to 12 and high alkalinity. They are enriched in HCO_3^- and CO_3^{2-} (carbonate ions) and borates. Soda lakes are usually saturated in sodium carbonate (Na_2CO_3), sodium chloride (NaCl), and sodium sulfate (Na_2SO_4). Soda lakes form in arid and semiarid areas of tropical and subtropical deserts of North America, continental Asia, and East African Rift Valley. Despite the extreme caustic conditions, soda lakes are the most productive aquatic environments on Earth, mainly because unlimited amount of CO_3^{2-} in solution. Microbial communities are studied in soda lakes as a possible analogue for ancient life on Earth, while soda lake chemistry is studied as an alternative model for the early ocean chemical evolution.

Overview

As the name indicates, soda lakes are characterized by the occurrence of large deposits of sodium in the form of carbonates such as trona ($\text{Na}_3\text{H}(\text{CO}_3)_2 \cdot 2\text{H}_2\text{O}$), natron ($\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$), thermonatrite ($\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$), halite (NaCl), and thenardite (Na_2SO_4). They are very alkaline with pH never below 10.5, with the highest values of pH = 12 recorded at Magadi Lake, Kenya. These conditions derive from a peculiar mixture of geographical, geological, and climatic conditions. Soda lakes are formed in very arid environments, often in depressions located above sea level and formed by continental rifting and with few or no freshwater inflow. Soda lakes occur worldwide but occur predominantly in the desert environments of Western North America (Soda Lake, Mojave Desert), inland Asia (North Tibet, Mongolia, Siberia), and the East African Rift Valley (Magadi and Natron Lakes, Kenya). The geology of the surrounding rocks, particularly the presence of rocks very depleted in Ca^{2+} and Mg^{2+} ions, plays a key role in the development of alkalinity. In most lacustrine environments, water rapidly becomes saturated with respect to Ca^{2+} , resulting in the precipitation of calcite (CaCO_3), magnesite (MgCO_3), and dolomite ($\text{MgCa}(\text{CO}_3)_2$) and preventing alkalinity. If the

CO_3^{2-} concentration exceeds that of Mg^{2+} and Ca^{2+} , alkalinity increases, and rock-available Na precipitates as halite and sodium carbonate.

Soda lakes are extreme environments for the strong alkalinity and high salinity of the waters. They are studied in astrobiology for three main reasons. Though living in caustic waters, a prolific ► [prokaryote](#) life develops in soda lakes, because of the high luminosity, high temperatures, and mostly unlimited supply of nutrients in form of dissolved CO_2 (CO_3^{2-}). Grant (2006) listed more than 60 species of living prokaryotes among ► [cyanobacteria](#), ► [archaea](#) (► [methanogens](#), thermophiles, and halobacteria), sulfur oxidizers, and anoxygenic phototrophs.

The possible occurrence of similar soda lake habitats on Mars in the past (Kempe and Kazmierczak 1997) makes these prokaryote communities an analogue for ancient life on Mars. Studying the chemistry of these lakes is also important because it has been proposed that ancient oceans were alkaline, as a consequence of the relative high amount of CO_2 in the atmosphere (e.g., Kasting 2011) and dissolved in the ocean, which promoted weathering of the basaltic crust of the early Earth, where Na^+ ions dominated over Ca^{2+} (Kempe and Degens 1985). Weathering of basalt plagioclase promotes precipitation of sodic carbonates, rendering alkaline the ocean. Although the hypothesis of Kempe and Degens (1985) on alkaline early oceans has been progressively dropped, very recently Toner and Catling (2020) proposed the existence of early carbonate-lakes which could have provided phosphorus for first living organisms. Phosphate is central to the origin of life because it is a key component of nucleotides, phospholipid cell membranes, and energy transfer molecules such as ATP (adenine triphosphate) which might be one of the candidates among the first metabolic pathways developed by LUCA (Last Universal Common Ancestor). Yet, in natural environments phosphorous is very rare because tend to precipitate as apatite in the geological record. In contrast, soda lakes contain large amounts of phosphorus making carbonate-rich lakes as plausible settings for the origin of life (Toner and Catling 2020).

Finally, the alkaline Lake Magadi, Kenya, contains chert deposits (Magadi chert), which are likely formed inorganically from sodium silicate

precursors (magadiite $\text{NaSi}_7\text{O}_{13}(\text{OH})_3 \cdot 3\text{H}_2\text{O}$ and/or kenyaite $\text{NaSi}_{11}\text{O}_{20.5}(\text{OH})_4 \cdot 3\text{H}_2\text{O}$). They have been often cited as modern analogues for inorganic-produced Precambrian ► [cherts](#) found in iron formations (Schubel and Bruce 1990).

Sol

Tilman Spohn
International Space Science Institute, Bern,
Switzerland

Definition

A sol is a solar day on another ► [planet](#) or other body orbiting the sun. It is the time between two successive returns of the ► [Sun](#) to the same local meridian.

Cross-References

- [Planet](#)
- [Sun \(and Young Sun\)](#)

Solar Constant

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Synonyms

[Total solar irradiance](#); [TSI](#)

Definition

The solar constant is the amount of total solar electromagnetic power that crosses a unit area perpendicular to the rays, at the mean distance from the Sun to the Earth. Its average value is $1,367.7 \text{ W m}^{-2}$. Despite its name, the solar constant is not exactly a constant and its fluctuations, most accurately measured since 1978, are of the order of one part in a thousand and are correlated with the 11-year cycle of the solar activity. They are also correlated with climate variations; however, they are too weak by a factor 3–6 to explain the

temperature variations on Earth. A planet-dependent solar constant has also been defined in the case of other solar system planets such as Mars.

Solar Luminosity

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The solar luminosity is defined as the total power emitted by the Sun in the form of electromagnetic radiation. The currently accepted value is $3.839 \times 10^{26} \text{ W}$. This is the most common unit used to express the luminosities of other stars or bigger objects such as galaxies or clusters of galaxies. Note that the Sun is a weakly variable star, with its luminosity fluctuating periodically by about a part in a thousand over the 11-year solar (sunspot) cycle.

Cross-References

- [Bolometric Magnitude](#)

Solar Mass

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The solar mass is defined as the total mass of the Sun. The currently accepted value is $1.99 \times 10^{30} \text{ kg}$. This is the unit commonly used to express the mass of huge astrophysical objects: stars, galaxies, black holes, dark matter.

Solar Nebula

Avi M. Mandell

NASA Goddard Space Flight Center, Greenbelt,
MD, USA

Definition

The solar nebula is the original ► [protoplanetary disk](#) from which the Solar System formed. The solar nebula itself formed from a pre-stellar cloud during the collapse phase of the Sun's formation. The solar nebula had an initial composition similar to that of the outer layers of the present Sun and had a minimum mass sufficient to form the current planets. The latter model nebula is known as the “minimum-mass solar nebula” (MMSN), which is estimated by adding enough light elements to the masses of all the planets to bring them to solar composition.

Solar Neighborhood

Leticia Carigi

Instituto de Astronomía, Universidad Nacional
Autónoma de México, Ciudad de México,
Mexico

Keywords

Milky Way · Stellar populations · Exoplanets

Synonyms

[Solar vicinity](#)

Definition

The solar neighborhood is the space associated with a cylinder centered at the Sun and perpendicular to the Milky Way disk. This solar cylinder is located at 8.2 kpc from the galactic center, with a radius of ~ 1 kpc. Hence, the solar vicinity includes diverse physical entities that belong to the galactic disk and halo, such as planets and moons; stars of different masses, ages, chemical elements, and evolutionary stages; interstellar medium of different properties: HII regions, neutral gas, molecular gas, and dust; among others.

Overview

The solar neighborhood contains baryonic matter (stars and gas) and dark matter. The total mass surface density is roughly $70 M_{\odot} \text{ pc}^2$, of which the stars take 50%, 20% is in gaseous material, and 30% is in dark matter.

The solar cylinder contains two main baryonic structures: first, a *disk component* where approximately 98% of the total stellar mass of the solar neighborhood is found in Population I stars embedded in metal-rich gas. They are located between ~ 1400 pc above and below the central plane of the disk, and secondly, a *halo component* formed by the older Population II stars and no gas, located beyond the disk.

The first component (*disk*) in turn shows two subcomponents. One is a thin disk of 350 pc formed by a young stellar population with an average age of 3.8 Gyr and an average metal content around the solar metallicity ($Z_{\odot}$), and interstellar gas with $1.2 Z_{\odot}$. Another is a thick disk of ~ 1000 pc thickness and formed by an older stellar population with age ~ 10.4 Gyr and a metallicity of $0.3 Z_{\odot}$. The mass of the thick disk is $\sim 12\%$ of the mass in the thin disk.

The solar neighborhood stars show basic relations to understanding the chemical evolution of galaxies: (1) an age-metallicity relation, such that low age correlates with high metallicity; (2) a metallicity distribution function that exhibits different peaks, as a combination of Gaussian curves (Bell curves), corresponding to the halo and disk stellar populations.

However, the relation presents a spread in ages for a fixed value of Z and the Gaussian functions show skewness (asymmetries). The main causes for these are not clear yet, but the explanation could be outside the solar vicinity: some stars could have migrated from other places of the Milky Way and some would have belonged to satellites galaxies accreted to the Milky Way.

Moreover, those stars show another important evolutionary relation, involving α/Fe versus Fe/H , where α represents an alpha-chemical element (e.g., O, Mg, Si, S, Ca, and Ti). This relation has led to elucidating several questions, such as the chemical contribution in time by massive stars (the main producers of α elements) and by thermonuclear supernovae (the main producers of Fe), the star formation efficiency, and the different scenarios for galactic formation for the Milky Way. The thick disk stars exhibit overabundances of α elements compared to the thin disk stars with the same Fe abundance, and the halo stars show a large scatter in α/Fe , reaching up to the extreme ratios of the thick and thin disk stars.

Due to the current methods for exoplanet detection, most of the extrasolar planets have been found in stars at distances from the Sun closer than 1.5 kpc, and mainly in the disk component of the solar vicinity.

The solar neighborhood is the astronomical laboratory for studying the properties of the stellar populations and of the interstellar medium.

There are other definitions of the solar neighborhood in the literature, for instance, (1) the region within 0.2 pc, where the planets, minor bodies, and the Oort cloud of the solar system are; (2) the region up to 100 pc from the Sun, where the closest stars are; and (3) the region up to 20 Mpc from the Milky Way, where the galaxies of the local cluster are.

Solar Particle Events

M. A. Shea
Air Force Research Laboratory (Emeritus),
Bedford, MA, USA

Keywords

Solar activity · Solar composition · Solar cosmic rays · Solar cycle · Solar protons

Synonyms

SPE

Definition

Ions and electrons that are accelerated by major solar activity and propagate through the interplanetary medium.

History

Major high energy events were first detected by ground-based detectors in 1942. Routine measurements of lower energy protons by spacecraft instrumentation commenced in 1965.

Overview

Solar particle events occur when activity on the Sun such as a solar flare and/or a coronal mass ejection accelerates and releases particles into the interplanetary medium. The actual process of solar particle acceleration is still under debate although it is most likely some type of shock acceleration process.

The frequency of solar particle events is correlated with the solar activity cycle although there is a large variance in the distribution. Major solar particle events consist primarily of sizable fluxes of energetic electrons and energetic protons with a small and variable flux of heavier elements. Protons are the most abundant ions. While most solar protons have energies less than 100 MeV, energies greater than 25 GeV have been identified. The flux and spectrum of solar particle events are not well correlated with solar activity parameters. Typical spectral slopes of solar particle events have values of -3 , with a large variation between events. Simple power laws or exponentials are generally not adequate to depict spectra over many orders of magnitude.

There are two general types of solar particle events frequently delineated by the duration of the associated solar X-ray emission. Solar particle events associated with solar flare impulsive X-ray events are generally small events detectable only over a limited range of heliolongitudes from the solar active region site. The elements in these events have an ionization state that is consistent

Solar Particle Events, Table 1 Normalized “average” solar particle composition

Charge	Species	Normalized abundance
$Z = 1$	Protons	1.0
$Z = 2$	Alpha particles	$1.5 \times 10^{-2} \pm 50\%$
$Z = 6$	Carbon	1.3×10^{-4}
$Z = 7$	Nitrogen	3.7×10^{-5}
$Z = 8$	Oxygen	2.4×10^{-4}
$Z = 26$	Iron	3.4×10^{-5}

with a ten million Kelvin plasma source. Solar particle events associated with fast coronal mass ejections are much larger events and can be detected over a range of heliolongitudes often in excess of 180° . As the coronal mass ejection driven shock moves outward from the sun through the interplanetary medium, additional acceleration of the ambient particle flux occurs, and this is often observed as a particle increase as the fast interplanetary shock moves past an observation position. These larger events with a proton flux that can exceed $100 \text{ particles cm}^{-2} \text{ s}^{-1} \text{ ster}^{-1}$ with energies $>10 \text{ MeV}$ have an elemental composition and charge state of the accelerated ions similar to that of the one million Kelvin solar corona. Table 1 gives the normalized “average” composition of these large events.

Solar Radius

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The solar radius is defined as the mean radius of the Sun. The currently accepted value is 6.955×10^8 m. This is the unit most frequently used to express the radius of other stars. Note that the Sun is very slightly oblate because of its rotation, by about 10 ppm.

Solar System

Tilman Spohn
International Space Science Institute, Bern,
Switzerland

Definition

The solar system may be defined as a system including all celestial objects which are subject to the gravitational field of the Sun. According to this definition, the solar system extends over a distance of about 2 light-years, or 0.65 pc, or about 120,000 AU. The most distant frontier that we know is the ► [Oort cloud](#), a spherical shell that extends beyond about 40,000 AU from the Sun, and is a reservoir for nonperiodic ► [comets](#). The solar system contains two main regions, the inner solar system between the Sun and the main asteroidal belt and the outer solar system beyond this limit. The inner solar system contains the ► [terrestrial planets](#) and their satellites and several families of ► [asteroids](#). The outer solar system contains the ► [giant planets](#) and their systems, distant asteroids (► [Centaurs](#)), and ► [trans-Neptunian objects](#). Most comets reside in the outer solar system

but some enter the inner solar system as they approach the Sun.

The solar wind is a flow of plasma emitted by the solar corona that fills the heliosphere and extends up to the heliopause, the frontier where the pressure from the solar wind equals the interstellar pressure. The heliopause has been detected by the ► [Voyager 1](#) spacecraft at a distance of about 120 AU from the Sun.

Solar System, Outer

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Definition

The informal phrase “outer Solar System” normally refers to the region of the ► [giant planets](#) and beyond, corresponding to distances from the Sun ≥ 5 AU. The outer Solar System thus also includes almost all ► [comets](#) during most of their orbital periods, as well as centaurs and objects in the ► [Kuiper Belt](#) and ► [Oort Cloud](#). As a result of the low temperatures in this region, solid objects contain a much higher percentage of volatiles such as water and other ices than the rocky objects closer to the Sun.

[Solar UV rays](#)

Definition

Solar ► [UV radiation](#) is the ultraviolet (UV) component of the solar extraterrestrial electromagnetic radiation that amounts to about 7% of the whole spectrum. Space experiments have shown that UVC (200–280 nm) is mainly responsible for the high lethality of extraterrestrial solar radiation to microorganisms exposed to it. Due to absorption by stratospheric ozone, only UV at wavelengths longer than 290 nm reaches the surface of the Earth. Several effects on human health and the integrity of ► [ecosystems](#) are caused by this UV range. In the Archean, before the buildup of the stratospheric ozone layer, UV at wavelengths shorter than 290 nm would have reached the Earth’s surface with the associated severe biological consequences.

Overview

The ultraviolet (UV) component of the extraterrestrial ► [electromagnetic spectrum](#) of our Sun can be divided into three spectral ranges: UVC (200–280 nm) contributing 0.5%, UVB (280–320 nm) contributing 1.5%, and UVA

(320–400 nm) contributing 6.3% to the whole solar electromagnetic spectrum, respectively. Although the UVC and UVB regions make up only 2% of the entire solar extraterrestrial irradiance, they are mainly responsible for the high lethality of extraterrestrial solar radiation to microorganisms exposed to it. This is due to the high absorption of those wavelengths by DNA, the decisive target within that UV range for inactivation and mutation induction. Experiments in space, such as on board of Apollo, Spacelab, LDEF, Foton, MIR, and ► [EURECA](#), as well as at space simulation facilities on ground, have shown that extraterrestrial solar UV radiation is biologically a thousand times more efficient than UV at the surface of the Earth and kills 99% of bacterial spores within a few seconds. In addition, a synergistic effect was observed in spores of *Bacillus subtilis* that were simultaneously exposed to solar UV radiation and space vacuum (Nicholson et al. 2000; Horneck et al. 2010).

Solar UV radiation undergoes absorption and scattering as it passes through the Earth's atmosphere, with the absorption by ozone being the most important process. As a result, no UV radiation at wavelengths shorter than 290 nm reaches the surface of the Earth. Several deleterious effects of sunlight on human health and ecosystem integrity are due to the Sun's UV emission that does reach the surface of the Earth. In addition, concern of an increase in solar UVB radiation has arisen in view of a gradual reduction in stratospheric ozone concentration, as already visualized by the ozone hole during austral spring. In humans, mainly the skin, the eye, and the immune system are influenced by increased UVB radiation; at the ecosystem level, most important effects are expected on aquatic ecosystems as marine primary producers (Diffey 1991; Häder 1997; Horneck and Baumstark-Khan 2002; Björn 2008). Without the stratospheric ► [ozone layer](#), as assumed to be the case for the Archean, UVC and UVB would have reached the Earth's surface with biologically effective doses three orders of magnitude higher than today (Cockell and Horneck 2001). A similar high biological effectiveness is assumed for UV at the surface of

► [Mars](#), which is bombarded with solar UV radiation of wavelengths longer than 200 nm (Cockell et al. 2000; Patel et al. 2004).

Solar UV radiation and its biological effects are important factors for considering the following astrobiological questions:

- How did solar UV radiation affect chemical evolution and biological evolution on the early Earth?
- How does solar UV radiation influence the habitability of other planets, for example, the surface of Mars?
- What is the impact of solar UV radiation on viable interplanetary transport of life by natural or anthropogenic processes?

 Météorologie Dynamique, BPParis, France

Definition

A quasispecies is a distribution of ► [mutant](#) genomes centered around one dominant or master

sequence. Quasispecies theory was developed by M. Eigen as a general model to understand the dynamics of the first replicative molecules in the context of the origin of information and the early evolution of life (Eigen [1971](#)). Although they were initially conceived as steady-state distributions of infinite size in equilibrium, quasispecies dynamics – characterized by a continuous process of mutant generation, competition, and selection – have also provided an interpretation of the great adaptive potential of RNA viruses (Domingo and Holland [1997](#)). Indeed, experimental evidence has shown that, due to their error-prone replication, different current biological entities behave as quasispecies: ► [viroids](#), RNA viruses, and DNA viruses that use RNA as an intermediate molecule during their replicative cycle. The response of the evolving viral quasispecies to selective pressures, e.g., immune response of the infected host or antiviral treatment, is influenced by the ensemble of mutants that compose the population (Lauring and Andino [2010](#)).

 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Definition

In chemistry and geology, a solidus is the set of temperatures below which a substance is completely solid or crystallized. The solidus defines the temperature at which a substance begins to melt, but not necessarily when the substance is completely melted. A solidus may be contrasted with a ► [liquidus](#). The solidus and liquidus may not be the same in all cases. When a difference exists between the solidus and liquidus temperatures, then in the intervening region, the system consists of a mixture of solid and liquid phases. In eutectic systems, solidus and liquidus temperatures are the same: The mixture melts completely at the eutectic point.

Space Environment

Gerda Horneck

DLR German Aerospace Center, Institute of Aerospace Medicine, Radiation Biology, Köln, Germany

Keywords

Galactic cosmic radiation · Solar extraterrestrial UV radiation · Space radiation · Space vacuum · Temperature in space

Definition

Space environment is the large void which occupies the (relatively) empty areas of the universe outside the atmosphere or surface of any planet or other celestial body. It is a vacuum that contains a low density of particles, as well as electromagnetic radiation, magnetic fields, and neutrinos. Based on our own perspective from planet Earth, the space environment is defined as the area beyond the atmosphere of the Earth. It is also considered as a branch of astronautics that addresses conditions of space that might affect the operations of spacecraft, the health of astronauts, and any other living being during space flight.

Overview

The space environment is characterized by a high vacuum, an intense radiation of galactic and solar origin, and extreme temperatures (Table 1).

Space Vacuum

In interplanetary space, vacuum reaches pressures down to 10^{-14} Pa. Within the vicinity of a body,

the pressure may significantly increase due to outgassing. In a low Earth orbit of an altitude below 450 km, which is the average altitude of the ► [International Space Station](#), pressure reaches 10^{-7} – 10^{-4} Pa. The major constituents of this environment are hydrogen, molecular oxygen, and molecular nitrogen as well as highly reactive oxygen and nitrogen atoms. In the vicinity of a spacecraft, the pressure further increases, depending on the degree of outgassing of the spacecraft itself. In the Space Shuttle cargo bay, a pressure of 3×10^{-5} Pa was measured.

There is no definite boundary between the atmosphere of the Earth and outer space. With increasing altitude, the atmosphere becomes thinner and eventually fades away into space (Fig. 1). The Kàrmàn line, at an altitude of 100 km, is often regarded as the “official” boundary for space human flights between the Earth’s atmosphere and space.

Space Radiation

The planets, moons, and small bodies in our solar system are continuously bombarded by charged particles coming from sources outside our solar system and from the Sun. The radiation field in interplanetary space is composed primarily of two types of radiation: galactic cosmic radiation (GCR) and solar cosmic radiation (SCR). GCR originates outside the solar system in cataclysmic astronomical events, and the particles are accelerated by supernova shock waves. They are composed of energetic particles, i.e., nuclei with all their orbital electrons stripped off, and have traveled for several million years through the galaxy before entering the solar system. GCR covers a broad spectrum of energy and mass values (Fig. 2). About 98% are atomic nuclei and 2% electrons and positrons. The nuclear component consists of about 87% protons, about 12% α -particles (He nuclei), and about 1% nuclei of an atomic mass $Z > 2$, the so-called ► [HZE particles](#). When these charged particles enter the solar system, they interact with the outbound streaming of the solar wind and its embedded interplanetary magnetic field which varies with the solar activity. In interplanetary space, the annual ► [radiation dose](#) amounts to ≤ 0.1 Gy depending on mass

Space Environment, Table 1 Parameters of interplanetary space and in low Earth orbit (LEO)

Space parameter	Interplanetary space	Low Earth orbit
Space vacuum		
Pressure (Pa)	10 ^{−14}	10 ^{−7} –10 ^{−4}
Residual gas (part/cm ³)	1 H	10 ⁴ –10 ⁵ H
		10 ⁴ –10 ⁶ He

Cosmic ionizing radiation		
Dose (Gy/a)	≤0.1 ^c	0.1–10,000 ^d
Temperature (<i>K</i>)	>4 ^a	Wide range (153–393) ^e
Microgravity (<i>g</i>)	<10 ^{−6}	10 ^{−3} –10 ^{−6}

^aDepending on orientation and distance to the Sun
^bAbove the Earth atmosphere
^cDepending on shielding, highest values at mass shielding of 0.15 g/cm²
^dDepending on altitude, orbit, and shielding, highest values at high altitudes, during frequent passages through the SAA of the radiation belts and through the polar horns, and shield of 0.15 g/cm²
^eDepending on orientation to the Sun and albedo of the body

shielding with the highest dose at 0.15 g/cm² shielding due to built-up radiation (Table 1). With increasing solar activity, the interplanetary magnetic field increases, resulting in a decrease of the intensity of GCR of low energies. Hence, the GCR fluxes vary with the solar cycle and differ by a factor of approximately three between solar minimum and solar maximum with a peak level during minimum solar activity and the lowest level during solar maximum activity.

SCR consists of the low-energy solar wind particles that flow constantly from the Sun and the so-called ► [solar particle events](#) (SPEs) that originate from magnetically disturbed regions of the Sun and sporadically emit bursts of charged particles with high energies (up to several GeV). These events are composed primarily of protons and electrons with a minor component (5–10%) of α -particles and an even smaller component (1%) of heavy ions. SPEs develop rapidly and generally last for no more than a few hours at energies >100 MeV and up to a few days at low MeV energies.

In low Earth orbit (LEO), which reaches up to an altitude of 450 km, the Earth’s magnetic field provides a latitude dependent shielding against GCR and SPE particles, so they are primarily

experienced in high-inclination orbits. In LEO, the radiation field includes an additional component: the radiation belts, the so-called Van Allen belts (Fig. 2). These Van Allen belts in the vicinity of the Earth are a result of the interaction of GCR and SCR with the Earth’s magnetic field and atmosphere. They consist of two radiation belts that are comprised of electrons and protons as well as some heavier particles trapped in closed orbits by the Earth’s magnetic field. The main production process for the inner belt particles is the decay of neutrons produced in cosmic particle interactions with the atmosphere. The outer belt consists mainly of trapped electrons and low-energy protons. In each zone, the charged particles spiral around the geomagnetic field lines and are reflected back between the magnetic poles that act as mirrors. Electrons reach energies of up to 7 MeV and protons up to about 200 MeV (Fig. 2). Of special importance for LEO missions is the so-called South Atlantic Anomaly (SAA), a region over the coast of Brazil, where the radiation belt reaches as low as 200 km above the Earth’s surface. This behavior is due to an 11° offset of the Earth’s magnetic dipole axis from its rotation axis and a 500 km displacement toward the Western

Space Environment, Fig. 1 Altitude profile of the Earth's atmospheric components and pressure

Pacific, with corresponding significantly reduced field strength values. The inner fringes of the inner radiation belt come down to the altitude of LEO, which results in a thousand times higher proton flux than in other parts of the orbit. Almost all radiation received in LEO is due to passages through the SAA. This complex radiation field experienced in outer space cannot be simulated

by any ground-based facility. The ► [radiation doses](#) in low Earth orbit and on Earth-Moon transfer have been measured since the beginnings of space flight activities (Swenberg et al. 1993; Reitz et al. 2009). Figure 3 reflects the increase of the space radiation dose with altitude of the Earth. At the surface of the Earth, the atmosphere provides a shielding of 1,000 g/cm².

► [Mars](#) has currently no planetary magnetic field and therefore also no radiation belts. The only radiation shielding is due to the Martian atmosphere, the thickness of which varies with surface altitude from 16 to 8 g/cm². Higher altitudes are less shielded; low altitudes such as Hellas Planitia are more shielded. Dose rates range from 200 to 300 mSv/year. The ► [radiation doses](#) expected during Earth-Mars transfer have been measured during the 2001 NASA Mars Odyssey mission (Zeitlin et al. 2004).

Jupiter has a strong global magnetic field. The Galilean satellites Io, ► [Europa](#), Ganymede, and Callisto are embedded within Jupiter's magnetosphere, and Io is known as a source of ions and neutral particles. Jupiter's inner radiation belt is analogue to the Earth's Van Allen belts, but about 10,000 times more intense. Europa is therefore continually bombarded by magnetically trapped ionizing radiation reaching an electron dose rate at its surface of several gray per minute (Baumstark-Khan and Facius 2002).

Solar Electromagnetic Radiation

The spectrum of solar electromagnetic radiation spans over several orders of magnitude, from short wavelength X-rays at 0.01 nm to radio frequencies at mm wavelengths. At the average distance of the Earth (1 AU), solar irradiance amounts to 1,370 W/m², which is the ► [solar constant](#). Of this radiation, 45% is attributed to the infrared fraction, 48% to the visible fraction, and 7% to the ultraviolet range. The extraterrestrial solar spectral UV irradiance has been measured during several space missions, such as Spacelab 1 and ► [EURECA](#) (Labs et al. 1987).

On its way through the Earth atmosphere, solar electromagnetic radiation is modified by scattering and absorption processes. Numerous lines of isotopic and geologic evidence suggest that the

Space Environment,
Fig. 3 Increase of the environmental radiation dose with altitude of the Earth

Archean atmosphere was essentially anoxic. As a result, the amount of ozone in the stratosphere, if any, would have been insufficient to affect the surface UV radiation environment. Thus, UV radiation at wavelengths >200 nm would have penetrated to the Earth’s surface with its associated biological consequences (Cockell and Horneck 2001). It took more than 2 billion years, until about 2.2 billion years ago, when as a consequence

of oxygenic photosynthesis, the Earth’s atmosphere was subject to rapid oxidation, and hence a stratospheric ► **ozone layer** was photochemically formed. This UV screen allowed life to colonize the surface of the Earth. Today, the stratospheric ozone layer effectively absorbs UV radiation at wavelengths shorter than 290 nm (Fig. 4).
For Mars, the solar constant is only 43% of that for Earth. However, the very low concentrations

Space Environment,

 conditions (Modified from
 Horneck et al. 2010)

of oxygen in its atmosphere prevent the formation of a stable UV-absorbing planetwide ozone layer. The energy-rich short wavelengths of solar UV radiation penetrate the Martian atmosphere and lead to high surface fluxes of UV radiation with wavelengths longer than 200 nm in contrast to the conditions on Earth, where only wavelengths longer than 290 nm reach the surface. Therefore, the biologically effective dose rate of UV irradiation on the surface of Mars is up to three orders of magnitude higher than on the surface of the Earth (Cockell et al. 2000; Patel et al. 2002, 2004). The actual UV irradiance at a certain location on the surface of Mars varies depending on factors like dust cover, season, local time, and altitude (Patel et al. 2003).

Temperature of Bodies in Space

The temperature of a body in interplanetary space depends on its position and distance to the Sun and also on its albedo, surface, size, and mass. It is

determined by the absorption and emission of energy. In Earth orbit, the energy sources are the solar radiation (1,370 W/m²), the effects of Earth's albedo (480 W/m²), and terrestrial thermal radiation (230 W/m²). In Earth orbit, the temperature of a body can reach extreme values. In different space exposure experiments, the samples were subjected to temperatures in the range of 243–318 K (Horneck 1998; Rabbow et al. 2009).

Space Vacuum Effects

Gerda Horneck
DLR German Aerospace Center, Institute of
Aerospace Medicine, Radiation Biology, Köln,
Germany

Definition

The vacuum of interplanetary space reaches pressures down to 10^{-14} Pa. Within the vicinity of a body, the pressure significantly increases due to outgassing (e.g., in low Earth orbit, pressure reaches 10^{-6} – 10^{-4} Pa). Pressures below the vapor pressure of a certain material cause vaporization of atoms or molecules from the material's surface. In addition to water, sealants, lubricants, and adhesives are the main substances that outgas from spacecraft. However, even metals and glasses can release gases from cracks and impurities. For biological samples in space, vacuum dehydration is the main process affecting their integrity.

Space Weathering

Harald Hoffmann
DLR, Institute of Planetary Research, Berlin,
Germany

Keywords

Cosmic rays · Exospheres · Micrometeorite impacts · Optical alteration · Solar wind · Sputtering

Definition

Space weathering describes all the effects caused by the interaction between the surface of an airless planetary body and the space environment.

Overview

The term space weathering summarizes alteration processes on an atmosphereless planetary surface due to the interaction of the surface material or regolith with the ► [space environment](#). As the direct contact layer between the planetary body and space, the surface is permanently reworked and physically and/or chemically modified by micrometeorite impacts, galactic and solar cosmic rays, solar irradiation, and the solar wind. These weathering processes may strongly affect the optical properties of the surface material and have to be taken into account in the analysis of remotely sensed observations.

The planetary surface is pulverized and turned over by a continuous micrometeorite bombardment. Depending on the kinetic energy involved, micrometeorite impacts may result in the melting of material and the formation of glass-welded aggregates (agglutinates), known as a major constituent of the lunar regolith, as well as glass splashes on single grains. Impact-related vaporization and sputtering due to the interaction with highly energetic particles can generate thin rims on individual grains. The reduction of iron in

silicates like olivine or pyroxene can result in the formation of metallic nanophase (single-domain) iron within these rims or glassy materials. Collisions with cosmic rays and the solar wind can also form tracks and result in the implantation of particles like ► [hydrogen](#), helium, and other rare gases. Space weathering processes result in the maturation of a planetary regolith over time until a steady-state equilibrium is reached and as long as fresh material is not excavated by a large impact.

Optical alterations due to space weathering of terrestrial planetary surfaces are mainly associated with the formation of single-domain iron and of glassy material. The spectral signature becomes darker, diagnostic absorption features weaker, and the spectral curvature redder. Similar effects have been reported not only for the ► [Moon](#) but also for ► [Mercury](#), the Martian ► [satellites](#), and some ► [asteroids](#). Pulverization and gas implantation are more effective for determining the spectral characteristics of icy satellites.

Space weathering processes are also responsible for the formation of the tenuous atmospheres (exospheres) found around, e.g., the Moon or Mercury, which consist mainly of Na^+ and K^+ ions.

Spallation Reaction

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

Spallation reactions are ► [nuclear reactions](#) where a high-energy projectile (usually a proton, neutron, or alpha particle) fragments a heavy nucleus, removing one or more nucleons from it and producing lighter nuclei. Such reactions occur during the propagation of cosmic rays in the galaxy's ► [interstellar medium](#). Spallation of abundant CNO nuclei is the main nucleosynthesis mechanism producing the light and fragile nuclides of Li, Be, and B, which are destroyed by thermonuclear reactions in stars (notice that ^7Li is also produced in the Big Bang and in stars, while some ^{11}B is, perhaps, produced through neutrino-induced nucleosynthesis). The abundance of particular spallation products on the surface of a meteorite provides a means of measuring the duration of its exposure to cosmic rays.

Keywords

High-speed ejection · Lithopanspermia · Meteorite impact

Synonyms

[Cavitation zone](#); [Interference zone](#); [Spall](#); [Spallation](#)

Definition

Spallation zones are regions adjacent to the free surface of a solid where the reflection of a strong incident stress wave induces tensile stresses and ejects material at high speed. The tensile stresses add to the compressive stresses in the incident wave and partially cancel its compression, leading to high-speed ejection of lightly compressed (“shocked”) material.

History

Spallation of the surface following impingement of a strong shock wave was first observed in association with underground nuclear explosions. During the 1980s, accumulated evidence indicated that the SNC suite of ► [meteorites](#) originated on a large planet, probably ► [Mars](#). Their

launch raised the conundrum of how intact rocks could be ejected at high enough speed to escape from Mars (a minimum of 5 km/s) and yet escape melting or vaporization. Melosh (1984) first suggested that spallation could provide the answer. Furthermore, Melosh (1988) suggested that the launch conditions might be gentle enough that microbes could survive interplanetary transfer inside the ejected rocks. This suggestion renewed modern interest in the ► [panspermia](#) idea.

Overview

The process of “spallation” is responsible for the high-speed ejection of rocks (often denoted “spalls” when produced by this process) from the surface of a planet near the site of a meteorite impact. While the ejection speed of the rocks may suggest that large compressive pressures are required by the Hugoniot equations that express the conservation of mass, momentum, and energy across a sharp shock front, the presence of a free surface drastically reduces the pressure in the incident wave near the surface (boundary conditions require that the normal stress on the free surface itself is exactly zero). This zone in which the reflected tensile wave adds destructively to the incident compressive wave is sometimes described as an “interference zone.” In a liquid, the same process produces an opaque “cavitation zone” that forms on the surface near underwater explosions. Away from the free surface, pressures rise rapidly to the level required by the Hugoniot equations. The distance over which this rise occurs is comparable to the diameter of the projectile but also depends on the distance from the impact site.

The existence of a spallation zone explains how nearly intact rocks can be ejected from the surfaces of such bodies as Mars (escape velocity 5 km/s) and the Moon (escape velocity 2.4 km/s), whose large escape velocities would normally imply that escaping material is melted or vaporized (Melosh 1984, 1985). Such rocks are the progenitors of the many dozens of meteorites that are now known to originate on Mars or the

Moon, some of which show little sign of the forces that ejected them (Head et al. 2002). Antarctic meteorite ► [ALH 84001](#) not only shows no sign of shock damage upon launch but, between its formation on Mars and its recovery on the Earth, did not experience temperatures greater than about 40 °C (Weiss et al. 2000). The spallation process has now been observed in the ejecta of large impact craters on Earth, in laboratory experiments, and in very high-resolution numerical simulations of impact.

The process of spallation allows viable microbes or microbial spores to survive launch from the surface of a planet into interplanetary space (Stöffler et al. 2007; Horneck et al. 2008; Fajardo-Cavazos et al. 2009). It may thus initiate interplanetary exchange of living organisms between planets in our solar system (Mileikowsky et al. 2000), although interstellar exchange seems very unlikely (Melosh 2003; Valtonen et al. 2009). This process of meteorite exchange between planets has variously been called panspermia or ► [lithopanspermia](#).

Spark Discharge

Jeffrey Bada
Scripps Institution of Oceanography, La Jolla,
CA, USA

Keywords

Cavendish · Electrodes · Miller

Synonyms

[Electric discharge](#)

Definition

A spark discharge is an electrical discharge between two electrodes that is used to simulate atmospheric lightning and coronal discharges. It

occurs when the electric field strength between the two electrodes exceeds a certain threshold value in volts per cm. This leads to a momentary increase in the concentration of ions between the two points, temporarily allowing the gases between the electrodes to serve as an electrical conductor.

Overview

Henry Cavendish did one of the first spark discharge chemistry experiments in the late eighteenth century. His investigations were designed to study aspects of atmospheric chemistry and showed that the action of a spark discharge in air resulted in the production of nitrous acid (Cavendish 1788). In Stanley Miller's classic 1953 experiment, a spark discharge acting on a mixture of hydrogen, methane, ammonia, and water produced HCN, aldehydes, and ketones, which in turn reacted by the Strecker reaction to form ► [amino acids](#).

Special Region (Mars)

Catharine A. Conley
NASA Headquarters, NASA Ames Research
Center, Washington, DC, USA

Definition

“Special Region” are locations on Mars that could be habitable for Earth life or be a habitat for Martian life. Currently, Special Regions are defined using the parameters of temperature and water activity. The specification as of 2020 is a location where (concurrently) the temperature reaches above $-28\text{ }^{\circ}\text{C}$ and the water activity is above 0.5 (relative humidity above 50%).

In accordance with the planetary protection policy maintained by the COSPAR, these Special Regions define a new category (Category IVc) of Martian mission. For those missions that investigate Martian Special Regions, even if they do not include life detection experiments, all of the requirements applicable to a surface mission to Mars (Category IVa) apply, along with the following requirements:

- Case 1. If the landing site is within the Special Region, the entire landed system is restricted to a surface bioburden level of $\leq 30^1$ spores.
- Case 2. If the Special Region is accessed through horizontal or vertical mobility, *either*

¹This figure takes into account the occurrence of hardy organisms with respect to the sterilization modality. This specification assumes attainment of Category IVa surface cleanliness, followed by at least a four order-of-magnitude reduction in viable organisms. Verification of bioburden level is based on pre-sterilization bioburden assessment and knowledge of the bioburden reduction factor of the sterilization modality.

the entire landed system is restricted to a surface bioburden level of $\leq 30^1$ spores, *or* the subsystems which directly contact the Special Region are sterilized to these levels, and a method of preventing their recontamination prior to accessing the Special Region shall be provided.

If an off-nominal condition (such as a hard landing) would cause a high probability of inadvertent biological contamination of the Special Region by the spacecraft, the entire landed system must be sterilized to a surface bioburden level of $\leq 30^1$ spores and a total (surface, mated, and encapsulated) bioburden level of $\leq 30 + (2 \times 10^5)^1$ spores.

At the present time, there are no areas accessible to spacecraft at the surface of Mars that are known to be Special Regions. However, recent surface features associated with fluid flow, particularly in low latitudes, have the potential to be Special Regions and are treated (under the precautionary principle) as though they are.

Pattern of recurrence · Taxonomic category ·
Unit of biodiversity

Synonyms

Lowest taxonomic category

Definition

In biology, species is the basic rank (category) supporting the taxonomic hierarchy that attempts to embrace all of the biological diversity present in the biosphere.

Overview

Aristotle first enunciated the idea of species about 2,400 years ago (fourth century before Christ). Linnaeus, in the eighteenth century, consolidated its use within a scientific framework and initiated the modern binomial classification. Since then, it has been used to identify each of the different biological units that can be observed in nature. As Jody Hey states, “species are categories motivated by recurrent observations about the world, and as humans are great observers of patterns of recurrence they devise categories as a response.” However, such patterns of recurrence are necessarily different for different kinds of organisms that exhibit distinct levels of morphological and/or physiological complexity. The idea of what a species may be depends on the type of organisms under study and the ability of the taxonomists to identify the phenotypic, genetic, and ecological singularities that make a unit different from its closest relatives. For organisms exhibiting complex morphologies such as plants and animals, the circumscription of the unit is mainly based on simple, easily recognizable, observable traits requiring no experimentation on living specimens. However, for morphologically simpler organisms such as prokaryotes and some microscopic eukaryotes, simple ocular examination is insufficient. In such taxonomies, there is a need to experiment with living specimens in the laboratory in order to retrieve enough genetic and phenotypic information to establish the taxa boundaries.

Over the years, philosophers and taxonomists have insistently tried to formulate the essence of what this biological unit could be. However, the search for a universal concept that describes the basic taxonomic rank soon became the focus of strong debates. Hitherto, more than 25 different concepts have been formulated. The most widely

known is the “biological species concept” (BSC) by Ernst Mayr who understood “species as groups of actually or potentially interbreeding natural populations which are reproductively isolated from other such groups.” However, while this concept works for most animals, it is not applicable to the vast majority of the biological entities that do not reproduce sexually. Among the different concepts formulated, scientists debate between the use of those of high theoretical load (such as “evolutionary” (ESC) or “cohesive” (CSC) species concepts, both considered synonyms) and those that can be considered theory-free (such as the “phenetic” (PhSC) or the “polythetic” (PtSC) species concepts, both considered synonyms). The former formulates that species is “an entity composed of organisms which maintains its identity from other such entities through time and over space, and which has its own independent evolutionary fate and historical tendencies”; the latter is formulated as “a similarity concept based on statistically co-varying characteristics which are not necessarily universal among the members of the taxa.” The success of the PhSC or PtSC is mainly based on the achievement of as many independent characters as possible. However, neither concept is well accepted. The ESC or CSC is very difficult to apply, and the PhSC or PtSC lacks a theoretical background.

Each discipline in biology creates its own classification and especially tailors its species circumscriptions in a manner that best fits the patterns of recurrence that they observe. Either we admit that biological diversity is so vast and evolutionary constraints are so varied among different biological lines of descent that a variety of species concepts are necessary to accurately capture the complexity of variation patterns in nature (pluralistic view) or if we want to achieve a universal concept that takes into account all biological diversity (monistic view), we have to admit that the concept of species may lack applicability and may not be operative.

As a final remark, we can consider species as each of the recurrence patterns that humans observe in nature, each of them having a different evolutionary fate. The ability to recognize species depends on the biological complexity of the

organisms under observation and the technological capacities available to recognize their unique properties. The final circumscription of a species will depend on the scientists’ abilities to recognize genetic and/or phenotypic complexities.

Classification · Phylogeny · Average Nucleotide Identity · Digital DNA-DNA hybridization · Genomic indexes · Taxonomy

Definition

A species is a category that circumscribes a (preferably) monophyletic and genomically coherent group of individual isolates/strains sharing a high degree of similarity in (many) independent features, comparatively tested under highly standardized conditions (Rosselló-Mora and Amann 2001).

Overview

Species is the basic unit and most important taxonomic rank in prokaryote classification, represented by a group of microorganisms that share a common ancestor (monophyly) and have a genotypic relationship and coherent phenotypic features. The concept of species in prokaryotes is quite complex, since it is based on the premises of the species adopted for higher organisms, which are differentiated by the inability of reproduction among the organisms. However, this concept cannot be applied to prokaryotes, which is able to exchange genetic material easily among different species. Besides, morphologically they are not so diverse, and thus the relative morphologic simplicity of most prokaryotic microorganisms implies that morphology is, in general, of little importance in contrast with the classification of higher organisms. A species is represented by a type strain, a designated strain that is used as a reference specimen and as a permanent example of the species.

Traditionally, the definition of species in prokaryotes was based on the determination of the DNA-DNA hybridization values and ΔT_m . It was generally accepted that strains with approximately 70% or greater DNA-DNA relatedness and with 5 °C or less ΔT_m should be considered as members of the same species (Wayne et al. 1987). However, certain drawbacks with respect to reproducibility, workability, and rigid application of DNA-DNA hybridization were reported (Stackebrandt et al. 2002). For those reasons, the prokaryote species delimitation has been based on a polyphasic approach which included phenotypic, genotypic, chemotaxonomic, and

phylogenetic features. Phenotypic characteristics should agree with DNA-DNA hybridization values, and it was recommended that a distinct genospecies that cannot be differentiated from another genospecies on the basis of any known phenotypic property not be named until they could be differentiated by some phenotypic properties.

In recent years, new methods and techniques have been proposed to supplement or supplant the experimental DNA-DNA reassociation technique. The most extensively used is the 16S rRNA gene sequence analysis, a molecular marker to establish relationships among nucleotide sequences in the definition of prokaryotic species. On that basis, it was proposed that strains sharing 16S rRNA gene similarities below 97% could be considered as different genospecies (Stackebrandt and Goebel 1994). More recently, this percentage has been fixed on a 98.7%, (Kim et al. 2014; Chun et al. 2018), requiring a high quality of the 16S rRNA gene sequences under investigation (Chun et al. 2018). However, comparative studies clearly reveal the limitations of the sequence analysis of this highly conserved gene in the determination of relationships at the strain level. To overcome these limitations, MultiLocus Sequence Analysis (MLSA) based on conservative protein-coding genes, called housekeeping genes, had been developed for its applicability to genomically circumscribe the taxon species and differentiating it from neighboring species. Such genes should be at diverse chromosomal loci and widely distributed among taxa.

A more recent approach that advances the species definition for prokaryotes, as it is currently widely accepted, is based on the whole-genome sequence analysis, by using the Overall Genome Related Indexes (OGRI). The Average Nucleotide Identity (ANI) and digital DNA-DNA hybridization (dDDH) are the most widely used. It has been estimated that ANI values of approximately 95–96%, and dDDH 70%, respectively, corresponded to the traditional 70% DNA-DNA reassociation standard of the current species definition (Konstantinidis and Tiedje 2005; Goris et al. 2007; Richter and Rosselló-Móra 2009; Meier-Kolthoff et al. 2013; Chun et al. 2018).

Specific Activity

Dionysis Foustoukos

Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC, USA

Definition

Specific activity is a measure of the reactivity of a compound per unit mass under specific physico-chemical conditions. For example, the specific activity of an enzyme, used to assess enzyme purity, is defined as the amount of substrate converted through enzymatic processes per unit of time and mass of the total protein (e.g., $\mu\text{mol min}^{-1} \text{mg}^{-1}$). For a system containing a specific number of radionuclides, specific activity describes the number of decay events per unit time per mass or, equivalently, the product of the number of nuclides by the decay constant (Becquerel or counts per second).

Synonyms

Evolutionary sequence of young stellar objects

Definition

Young stars and their protostellar precursors are referred to as “young stellar objects” (YSOs) (Strom 1972), by astronomers since they are often deeply embedded in circumstellar dust and invisible at optical wavelengths. While most of them cannot be placed in the Hertzsprung-Russell diagram, YSOs can be organized along an empirical evolutionary sequence based on the shape of their spectral energy distributions (SEDs) from near-infrared to submillimeter wavelengths. Four broad classes of YSOs are distinguished (Class 0 → Class I → Class II → Class III) as the peak of the SED shifts from the submillimeter to the optical domain.

History

With the development of near-► [infrared astronomy](#) in the 1970s, many YSOs heavily obscured by dust at optical wavelengths were discovered in nearby star-forming clouds (e.g., Strom 1972). In the 1980s, the launch of the infrared satellite *IRAS* and the advent of near-infrared detectors allowed extensive surveys for embedded YSOs to be carried out and nearly complete spectral distributions of radiated energy to be constructed. Lada and Wilking (1984) and Lada (1987) proposed to divide the observed YSOs into three distinct morphological classes (I–III), depending on the slope $\alpha_{IR} = d \log (\lambda F_{\lambda}) / d \log \lambda$ of their near-infrared to far-infrared spectral energy distributions (energy flux λF_{λ} vs. wavelength λ). Adams et al. (1987) suggested that this infrared classification scheme could be interpreted in terms of an evolutionary sequence. With the development of millimeter and submillimeter observations, a fourth class (Class 0) was

then added to accommodate the discovery of YSOs so deeply embedded that they radiate large amounts of far-infrared and submillimeter emission relative to their total luminosities (André et al. 1993).

Overview

Classification of Spectral Energy Distributions

It is convenient to describe the spectral evolutionary classification of YSOs (cf. Fig. 1) by going backward in time, starting from objects detected in the near-infrared and ending with objects only (or mostly) visible at far-infrared and submillimeter wavelengths. In the near-/mid-infrared, three broad classes of YSOs can be distinguished based on the index $\alpha_{IR} = d \log (\lambda F_{\lambda}) / d \log \lambda$ of the spectral energy distributions (SEDs) between ~ 2.2 and $\sim 10\text{--}25 \mu\text{m}$ (Lada 1987). Class III sources have $\alpha_{IR} < -1.5$ and display reddened starlike or blackbody-like energy distributions. Class II sources have $-1.5 < \alpha_{IR} < 0$, reflecting the presence of significant near-► [infrared excess](#) emission superposed on a typical stellar blackbody. Class I sources have $\alpha_{IR} > 0$ and thus rising SEDs toward long wavelengths, implying a huge excess of far-infrared emission compared to that expected from a stellar photosphere. When optically visible, Class III and Class II objects correspond to pre-main-sequence stars (“weak” and “classical” T Tauri stars, respectively). The SEDs of Class I sources are successfully modeled in the framework of the “classical” theory of isolated protostars (e.g., Adams et al. 1987), in agreement with the view that a substantial fraction of their luminosity arises from accretion of circumstellar material (e.g., Greene and Lada 1996). Using millimeter and submillimeter observations, younger protostars, corresponding to a fourth class of YSOs (Class 0), have been identified. Class 0 objects, whose SEDs peak longward of $100 \mu\text{m}$ in the submillimeter domain, are very weak and often even undetected at near- and mid-infrared wavelengths shortward of $25 \mu\text{m}$. These objects are characterized by high ratios of submillimeter to bolometric luminosity ($L_{\text{submm}}/L_{\text{bol}} > 1\%$) and overall SEDs

Spectral Classification of Embedded Stars, Fig. 1 Empirical sequence for the formation and circumstellar evolution of a single star from a prestellar cloud core to a Class III young stellar object, based on the shape of the

spectral energy distribution (*left*), the bolometric temperature, and the mass of circumstellar (envelope + disk) material indicated on the *right* (From Lada (1987), André et al. (1993, 2000), and Myers et al. (1998))

resembling 15–30 K blackbodies (André et al. 1993). The full sequence of SEDs from Class 0 to Class III objects is in fact quasi-continuous and may be conveniently parameterized by a

single parameter, the average or “bolometric” temperature (T_{bol}), defined as the temperature of a blackbody having the same mean frequency as the observed YSO SED (Myers et al. 1998).

Circumstellar Evolution

YSOs are composite objects made up of a growing central star, a circumstellar disk, a circumstellar envelope, and a bipolar outflow. The SED classification described above primarily tracks the evolution of the circumstellar components. The strong submillimeter emission of Class 0 sources relative to their total luminosity indicates that the circumstellar envelope is the dominant component at the Class 0 stage, with a mass that exceeds the mass of the central stellar object ($M_{\text{env}} \gg M_*$; André et al. 2000). Class 0 objects are thus excellent candidates for being very young accreting protostars in which a hydrostatic protostellar embryo has formed within a dense cloud core but not yet accreted the majority of its final mass. They represent a pivotal evolutionary stage in the path leading from interstellar cloud matter to solar systems like our own. Class I objects are still associated with dense molecular gas and derive their large infrared excesses from the presence of both a disk and a circumstellar envelope (Adams et al. 1987). Mapping at millimeter wavelengths confirms the presence of a significant envelope at the Class I stage but shows that this envelope is no longer very massive and often only a remnant of the parent prestellar core ($M_{\text{env}} < M_*$; André and Montmerle 1994). Class II and Class III objects lack a dense circumstellar envelope component and are only surrounded by a circumstellar disk (optically thick and optically thin at $\lambda < 10 \mu\text{m}$, respectively). While the disk is still massive enough to be protoplanetary in nature at the Class II stage ($M_{\text{disk}} \sim 0.01 M$ on average; Beckwith et al. 1990), it has evolved to an optically thin debris disk by the Class III stage.

Bipolar Outflows and Gravitational Infall

Class 0 sources are associated with powerful, highly collimated bipolar outflows (Bontemps et al. 1996; Bachiller 1996), which provide indirect evidence of the presence of a central protostar and distinguish Class 0 YSOs from prestellar cores, i.e., starless dense fragments within molecular clouds.

As a whole Class 0 objects drive much more powerful outflows than Class I sources of

comparable bolometric luminosities (Bontemps et al. 1996). Furthermore, the **bipolar flows** from Class 0 objects are much better collimated than those from Class I (and Class II) sources.

Class 0 protostars were the first YSOs for which convincing spectroscopic signatures of gravitational infall motions could be obtained, confirming their protostellar nature (see Evans 1999 for a review). While some infall is still present at the Class I stage, the outflow is so broad in Class I sources that there often appears to be little transfer of mass to the inner 2,000 AU radius region around these objects.

Although the accretion/ejection phenomenon is believed to be episodic, the observed outflow and infall properties are suggestive of a global decline in the mass accretion rate onto the central protostar from $\sim 10^{-6} - 10^{-5} M_{\odot}/\text{year}$ at the Class 0 stage to $\sim 10^{-7} - 10^{-6} M_{\odot}/\text{year}$ at the Class I stage. Despite substantial scatter, a general decline in mass accretion rate as a function of age is similarly observed among T Tauri stars from $\sim 10^{-7} M_{\odot}/\text{year}$ for the youngest Class II objects to less than $\sim 10^{-9} M_{\odot}/\text{year}$ for Class III sources (e.g., Hartmann 1998).

Time Evolution and Approximate Timescales

To summarize, combining observations at near-infrared to millimeter wavelengths makes it possible to distinguish two classes of protostars (Class 0 and Class I) and two classes of pre-main-sequence stars (Class II and Class III), which are interpreted as an evolutionary sequence (Class 0 $\rightarrow$ Class I $\rightarrow$ Class II $\rightarrow$ Class III). Statistical arguments based on the numbers of sources observed in the various classes suggest that the corresponding lifetimes run from $\sim 1-5 \times 10^4$ years for Class 0 protostars to $\sim 1-5 \times 10^7$ years for Class III young stars, increasing by roughly a factor of ~ 10 from one evolutionary stage to the next (e.g., André and Montmerle 1994; Greene et al. 1994; Evans et al. 2009). These lifetimes also provide very rough estimates of the typical ages of YSOs according to their SED class. This is only true in a statistical average sense, however, since the above-described classification corresponds to an

evolutionary sequence only for the circumstellar material and is not directly related to the evolution of the underlying stellar objects. For instance, when placed in the Hertzsprung-Russell diagram, a significant fraction of weak T Tauri stars (Class III objects) appears to be not older than, but coeval with, Class II objects (e.g., Stahler and Walter 1993). These relatively young Class III objects may have dissipated their circumstellar disks and infalling envelopes particularly early, as a result of, e.g., unusually strong fossil magnetic fields and/or the tidal effects of a close companion. To some extent, therefore, the circumstellar evolution of YSOs is decoupled from their purely stellar evolution.

Basic Methodology

The practical diagnostics that one uses to order YSOs and cloud cores along the evolutionary sequence sketched in Fig. 1 are the infrared spectral index α_{IR} or shape of the infrared SED (Lada 1987), the “bolometric” temperature T_{bol} of a source (Myers et al. 1998), and the mass of circumstellar (envelope + disk) material (e.g., André and Montmerle 1994). Independently of the details of any protostellar theory, and in a statistical sense at least, one expects young stellar objects to become warmer and to be surrounded by progressively smaller amounts of circumstellar material as they evolve. Accordingly, the peak of the SED moves from the submillimeter for prestellar cores and (cold, deeply embedded) Class 0 protostars, to the far-IR for Class I protostars, to the near-IR and the optical for pre-main-sequence stars (Class II and Class III sources) (see Fig. 1). In the case of embedded protostars, the decrease of circumstellar mass with time results from the progressive dissipation of the protostellar envelope through accretion and outflow. For instance, in all self-similar isothermal models of collapse, including the classical Shu et al. (1987) model, the mass enclosed within a given radius R of the infalling envelope scales approximately as $M_{\text{env}}(r < R) \propto t^{-1/2}$ with time.

Future Directions

While ground-based near-IR surveys, coupled with infrared and X-ray observations from space with the *IRAS*, *ISO*, *Spitzer*, *XMM-Newton*, and *Chandra* satellites, have provided a fairly complete census of YSOs from Class I to Class III in nearby clouds, no such census exists yet for Class 0 protostars and cold prestellar cores. Only about 30 Class 0 protostars are known to date and only four in the nearest clouds ($d < 150$ pc) (cf. André et al. 2000). Consequently, the ages and lifetimes of prestellar cores and Class 0 objects are very uncertain compared to those of pre-main-sequence stars and remain a matter of lively debate in the star formation community (e.g., Ward-Thompson et al. 2007; Evans et al. 2009). Wide-field imaging at far-infrared and submillimeter wavelengths (70–500 μm) with the *Herschel* Space Observatory, successfully launched by ESA in May 2009, will soon remedy this unsatisfactory situation by providing complete samples of prestellar cores and Class 0 protostars in nearby Galactic molecular clouds. The first results of *Herschel* are extremely promising and suggest that more than 5,000 prestellar cores and more than 500 Class 0 protostars will be identified by the end of the space mission (see Astronomy and Astrophysics Vol. 518, special feature on *Herschel*).

Spectral Line

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

A spectral line is a deficiency or excess of radiation at a precise wavelength in the spectrum of a source because of a quantum effect (transition between two energy states) in an atom, molecule, ion or functional group (in the case of a solid) present in the source. The terminology originated with the slit spectrometers used by physical scientists to display a spectrum. Each spectral line is very specific to a given species, so that it can be used to identify the chemical composition of the object emitting or transmitting the light analyzed with a ► [spectrometer](#). Comparing the intensities of different spectral lines provides information on physical conditions such as temperature and density. The displacement of spectral lines under the Doppler Effect allows astronomers to derive the velocity of the emitter (or absorber).

Definition

Parameters directly linked to spectral signatures of minerals of interest are known as spectral parameters. The idea is that a given spectral feature can be described by a single parameter value, calculated by applying an algorithm to the spectral data.

Overview

Spectral parameters are a useful tool for the scientific interpretation of spectral orbital and in situ data and a key for future mission landing site selection and operations. A spectral parameter has the intent to capture spectral features diagnostic of a specific mineralogy. For example, mineral

spectra contain absorption features diagnostic of the mineralogical composition. Spectral parameters can be derived from the absorption features present in the spectra, isolating each absorption band. Absorption features can, then, be parametrized by calculating, for example, the band depth. This parameter is defined as $\Delta = 1 - R_{\lambda}/R_{\lambda,*}$, where R_{λ} is the reflectance at the center wavelength of the band and $R_{\lambda,*}$ is the interpolated continuum reflectance at the same wavelength (Clark and Roush 1984). The continuum level is created from a linear fit between two wavelengths from either absorption sides that are part of the local continuum levels. A spectral parameter value can be mapped across a region of a planetary body surface to study spatial variations of the associated spectral feature. These variations are in turn interpreted as spatial variations of the associated mineralogy.

The use of spectral parameters to analyze spectral data has been adopted with success in past and more recent analyses of planetary spectral data (see, for example, Bell et al. 2000; Murchie et al. 2009; Viviano-Beck et al. 2014; Mancarella et al. 2017; Alemanno et al. 2021). In the case of Mars, a set of 60 revised spectral parameters have been published by Viviano-Beck et al. (2014). The dataset published from these authors includes parameters related to OMEGA spectral parameter calculations and new parameters that highlight locations of newly discovered spectral signatures thanks to CRISM data. The analysis performed by Viviano-Beck et al. (2014) shows how the revised set of summary products presented unable to capture the spectral diversity of the Martian surface. Indeed, several works identified minerals on the Martian surface using CRISM data thanks to the application of these spectral parameters.

Spectral Type

Sylvia Ekström
Observatoire Astronomique de l’Université de Genève, Faculté des Sciences, Université de Genève, CHVersoix, Switzerland

Definition

Stars are classified based on the ionization state of their atmosphere and thus on their surface temperature. From hottest to coolest, the classification goes as O, B, A, F, G, K, and M (with the mnemonic “Oh Be A Fine Girl/Guy, Kiss Me”):

Type	Temperature	Main lines
O	≥30,000 K	He II, C III, N III, O III, Si IV
B	10,000–30,000 K	He I, Mg II, Si II
A	7,500–10,000 K	H, Mg II, Fe II, Si II
F	6,000–7,500 K	H, Fe I, Cr I, Ca II
G	5,200–6,000 K	Fe I, Ca II, CH
K	3,700–5,200 K	Fe I, Si I, Mn I, TiO
M	≤3,700 K	TiO, VO, molecular

Each category has ten subdivisions numbered from 0 (hottest) to 9. The spectral type is usually complemented by the *luminosity class*, labeled in roman numbers from I (supergiants) to V (main sequence dwarfs); that is, stars of the same effective temperature may have differing luminosities, depending on their mass and evolutionary state.

The Sun has a spectral class G2V.

History

Historically, spectral types were assigned alphabetically primarily in an order reflecting the decreasing strength of hydrogen absorption lines in their spectra. Only later was it realized that the different spectral types resulted from differing surface temperatures.

Spectral Veiling of Young Stars

Steven W. Stahler
Department of Astronomy, University of California, Berkeley, CA, USA

Definition

Stellar spectra exhibit sharp absorption lines superposed on a smooth, background flux. The

pattern of lines reveals both the chemical elements present in the stars' surface layers and the temperature of this material. In classical ► [T Tauri stars](#), pre-main-sequence objects of solar mass and below, the absorption lines are partially filled in. This is referred to as veiling and is thought to represent emission from shocks created as material crashes onto the stellar surface. The degree of spectral veiling correlates with the amount of ► [infrared excess](#), which arises from heated dust grains in circumstellar disks. Indeed, the infall creating spectral veiling is thought to arise largely from such disks. Both features are absent in weak-lined T Tauri stars.

Definition

A spectrometer is an instrument used by scientists to decompose the radiation either emitted by a source or transmitted by a region or substance of interest, so as to measure the intensity as a function of the wavelength in a way that can be recorded. In the visible, it may be based on a prism or a grating; in the infrared, it can be a

Fourier transform technique which is used, and in the radio domain, it is generally an auto-correlator. It produces a spectrum (plural spectra) which is an accurate record of the intensity versus the wavelength.

Spectroscopic Orbit

David W. Latham
Harvard-Smithsonian Center for Astrophysics,
Cambridge, MA, USA

Definition

When two stars orbit each other and the orbital motion is detected spectroscopically from the changes in the Doppler shifts (also known as Doppler velocimetry), the system is traditionally called a spectroscopic binary. Accordingly, the orbital solution based on the observed changes in radial velocities of the two stars is called a spectroscopic orbit. When the companion is a planet, only the spectrum of the host star is detected. In this case, the planet and star revolve around their center of mass. Although the orbit of the primary star around the center of mass is smaller than that of the planet, it is still called a spectroscopic orbit. The five parameters that define a single-lined spectroscopic orbit are the orbital ► [period](#) P , the ► [eccentricity](#) of the elliptical orbit e , the velocity of the center of mass γ , the amplitude of the orbital velocity projected along the line of sight K , the orientation on the sky of the long axis of the ellipse ω , and the time of ► [periastron](#) passage T . When the orbit is circular, $e = 0$ and ω is not defined, so the time of maximum velocity away from the observer is used instead of T .

Radial velocities do not provide enough information to determine the orbital inclination, but do provide some information about the masses:

$$M_B \sin(i) = (M_A + M_B)^{2/3} f^{2/3}$$

Where f is the mass function and is given by

$$f = 1.036 \times 10^7 K_A P (1 - e)^{3/2}$$

M_A and M_B are the masses of the primary and secondary in solar masses, i is the orbital inclination (90° for an edge-on orbit), K_A is the observed semi-amplitude of the orbital velocity of the primary in km/s, P is the orbital period in days, and e is the orbital eccentricity. If the orbital inclination can be determined through other observations, then the $\sin(i)$ ambiguity can be removed. In a binary star, when the spectrum of the secondary star is also detected, the orbital amplitude of both stars can be determined, and thus the mass ratio $q = M_B/M_A = K_A/K_B$ can be obtained.

Definition

Spectroscopy is the technique used to measure the intensity of electromagnetic radiation as a function of either wavelength or frequency. Spectroscopy is an important tool to derive the physical and chemical properties of astronomical objects as well as their velocity. The study of spectral features from atoms, ions, and molecules is of particular importance to give access to abundances, temperature, pressure, magnetic field, radial velocity, etc. The term spectroscopy is also applied in other fields, for example, to the measurement of the abundances by mass of chemical species in a sample (see Mass Spectroscopy).

Overview

Light brings a wealth of information, which a blind person misses badly every day. Generally, we think of this information primarily in the form of images of the world around us that light carries to our retina or to the electronic retinas of our cameras. In astronomy, imaging is often the first phase of discovery to derive morphology, shape, size, and displacement. From the planets to the discovery of giant structures or filaments in the Universe, images have played a major role in astronomy. Light carries yet another crucial piece of information, perhaps richer than the image, its energy. A celestial object indeed registers in the light it emits a footprint, often very accurate, of its composition, its energy state, and its dynamics. On one hand, physical processes will produce photons following a well-defined energy distribution, depending on the physical conditions like temperature or elementary composition of the source (gas of electrons, atoms of different chemical species), and, on the other hand, internal or global movements of this source often subtly alter this distribution.

Whatever is the description of light, photons, or electromagnetic waves, its energy content is perfectly defined. A photon, the particle of light, is described by two parameters only: its energy E and its state of polarization. Energy is the most important parameter because it will drive all the basic properties of the photon-matter interactions. This energy is unchanged as long as the photon is *alive*, that is to say, is not absorbed. If we now consider an electromagnetic wave, the other complementary way to describe light, it carries power in the form of waves progressing very rapidly: at the speed of light of course! Two wave crests are separated at a given moment by a characteristic length, called wavelength, and always denoted by the symbol λ . E and λ are related to the simple law $E = hc/\lambda$, where c is the speed of light and h is a physical constant introduced by Max Planck. The wavelength is a quantity which results in a clearly discernible property that our brain can perceive in visible light, which is the color. For instance, dark red corresponds to a wavelength of 750 nm, typically two times larger than the wavelength of blue light.

Most generally the resulting emission of a given phenomenon is the superposition of several waves at different wavelengths, in fact a continuum. If in music the superposition of wavelengths makes the richness of the sound, in contrast, for the astrophysicist, the wealth comes from the separation into the basic components of the light. This separation or decomposition is essential to analyze the predominance of one portion of the wavelength domain or another or for seeking for *spectral lines* which are reinforcements (known as emission lines) or gaps at a particular wavelength (absorption lines). This information bears the mark of processes that gave birth to the light or have influenced it later and which allow the astrophysicist to go much further in the physical understanding of phenomena than is allowed by the image alone. Spectroscopy is the science of analyzing the light into its components, and it is customary to say that astrophysics, to distinguish it from conventional astronomy, was born in the middle of the nineteenth century with the advent of spectroscopy. It is always amazing to realize the extraordinary richness of the spectroscopic

information. It actually gives access to a wide variety of physical quantities: the velocity of an object or even the velocity distribution of its components (for instance, in a galaxy); the composition of the matter it is made of, atoms or molecules; the state of this matter (ionized, atomic, molecular, solid, gaseous); the temperature, density, or pressure of the gas; the intensity and direction of the magnetic field, etc. These quantities are then used by the astrophysicist to constrain physical models describing the objects and their interactions. Predictions are then proposed that new spectroscopic measurements will confirm or deny in a continuously repeated cycle.

Basic Methodology

Spectrographs. Spectroscopy uses dedicated instruments to decompose the light in order to produce a spectrum, i.e., a measure of the light intensity as a function of wavelength. Figure 1 illustrates a spectrum of sunlight in two forms: the colorful one that the eye sees in the spectroscope and the more quantitative one as a plot of light intensity as a function of wavelength. The instrument that makes this decomposition is a spectrograph or a ► [spectrometer](#); however, for the purist, the later term refers rather to an instrument that provides a direct and accurate calibration of the wavelength.

The prism spectrograph. The first spectrographs exploited the variation with wavelength of the optical index of materials to produce differential deviation of the light according to its color (its wavelength) when refracted by a prism. Figure 2 shows the basic elements of a prism spectrograph. Issued from a point source, whose extension is limited by a slit, a parallel beam is formed thanks to the first lens – the collimator; the beam falls then on the prism at a specific angle of incidence – and the second lens after the prism, the camera, reforms a series of distinct images of the source, each one at a given wavelength.

Among the disadvantages of the prism is the size it must have when one wishes to achieve a high resolution. Producing glass blocks of large volume, while guaranteeing a very good

Spectroscopy, Fig. 1 The visible spectrum of the Sun presented in two forms. *Top*: as it appears in a spectroscope, that is to say, as a bright band showing the colors of the rainbow and streaked with many lines more or less dark; *bottom*: a plot giving the accurate information of

the intensity versus wavelength in a narrow region. Note the significant depression in the spectrum at 656.6 nm: it corresponds to an absorption due to hydrogen (Doc: BASS 2000)

Spectroscopy, Fig. 2 The principle of a prism spectrograph: it includes a slit, a collimator (*double-headed arrow*), the prism, a camera lens (a *second double arrow*), and a detector on which the spectrum is formed

homogeneity of their optical properties, becomes a challenge. The absorption in the glass is another limitation. The prism spectrograph has been supplanted gradually by the grating spectrograph.

The grating spectrograph. The grating spectrograph uses the principle of light interference that stems directly from the wave nature of light. A grating is a reflective surface which has been engraved with a series of fine parallel grooves separated by very small distances, a few micrometers to a few tens of micrometers. If a beam of light falls on the surface, then each slot, because it is very small, will spread the light in all directions (the ► [diffraction](#) phenomenon). In a given direction, there is a unique wavelength for which the wavelets emitted by all the grooves are in phase and will therefore add, as shown in Fig. 3. In a direction somewhat different, waves at that wavelength are somehow out of synchronization, and, as there is a very large number of them, they cancel each other. A given direction is thus associated with a single wavelength whose intensity is preserved, while at all other wavelengths, the destructive phenomenon is extremely effective.

Spectroscopy, Fig. 3 The principle of the diffraction grating. Each groove engraved on the surface of the grating diffracts light in all directions. In a given direction, there is a single wavelength for which all the waves from the

different grooves are constructive. In the same direction but at a different wavelength, the waves are incoherent and destroy each other

Spectroscopy,

Fig. 4 Arrangement of the entrance slit, of collimator (here a spherical mirror), and of the grating in a grating spectrograph

Eventually, we obtain the desired effect: each wavelength is isolated in a given direction.

In practice, for a good separation of wavelengths, one looks for a large number of lines per unit length (about 40–200), a result obtained thanks to a very precise machine equipped with diamond tools. In addition, the grating is used at large angles of incidence of the beam on the grating. Significant progress has been made with the introduction of the *échelette* grating, so named because of the particular stair shape of the grooves: the facets that behave like small mirrors can better focus the light in the direction where the spectral analysis has to be done.

From the viewpoint of its implementation in a spectrograph, the grating is used in a manner quite similar to that of the prism: it is placed in the parallel beam issued from a collimator and a camera objective reforms the image of the entrance slit

on the detector, the slit being oriented parallel to the lines of the grating. Figure 4 illustrates this configuration.

Fourier transform spectrograph. Fourier transform spectroscopy is a clever use of the interference of light to derive the spectrum. The intensity of a beam containing all the different wavelengths of the studied light, but each with a different weighting, is measured by a unique detector. The weighting is due to interferences in a Michelson interferometer, an optical instrument that allows some wavelengths to pass through but blocks partially or totally others. By moving one of the mirrors of the interferometer, the interference structure and thus the weighting is changed, so that repeating the process many times produces as many data points as there are distinct wavelengths. However, this is not yet a spectrum, each measurement being a linear combination of

different intensities of the various wavelengths. Inverting the set of data to produce the spectrum is done with a computer, thanks to a rather simple algorithm called the Fourier transform. One advantage of the Fourier transform spectrograph is the capability to reach very high resolving power. It is becoming a widespread laboratory instrument to measure molecular or atomic spectra.

Performances of a spectrograph. Since the goal of a spectrograph is to separate the wavelengths, its main characteristic is its resolution or resolving power $R = \lambda/\Delta\lambda$, defined as the ratio of the central wavelength to the smallest difference in wavelength $\Delta\lambda$ between two *colors* that can be distinguished unambiguously. $\Delta\lambda$ is called the spectral resolution element. Figure 5 illustrates how the

Spectroscopy, Fig. 5 Observation of a spectral feature in a spectrum (a *double line* in absorption) when the resolving power increases: from a mere depression, one passes to the separation into two distinct components. The spectral resolution element is indicated by the *horizontal line* segment to the right of each curve

information becomes more accurate when the resolving power increases and thus the spectral resolution element becomes smaller. For a grating, one may show that the maximum resolving power is directly given by the ratio of the length of the grating to the wavelength. A large grating is thus required to reach a large resolving power.

The resolution of a spectrograph varies according to the goal to be achieved: for the spectroscopy of faint distant galaxies, a resolution of $R = 2000$ is well suited. In contrast, in spectroscopy of a bright source like the Sun, where extremely fine physical effects can be looked for, resolving powers of several hundreds of thousands are common. In ► [radio astronomy](#), heterodyne techniques can provide even much higher resolution.

A second element of performance is the wavelength range that a spectrograph is able to analyze at once. The size of the detectors often limits the spectral range. Note that the prism has the advantage over the grating in having a spectral range that is bounded solely by the transmission of the glass, while the grating is limited in principle to an octave or less if very high spectral resolution is the goal. However, a clever combination of optics can overcome this limitation and provides simultaneously broad spectral range and high resolution. The trick is to use a second grating or a prism of modest resolving power to disperse the light in a direction perpendicular to the primary dispersion, so that the spectrum is divided into bands that can cover the surface of a CCD detector with no overlap. This setup, called a cross-dispersed spectrograph, is more and more popular in astronomy, and, in particular, it is the choice instrument for the detection of exoplanets through ► [radial velocity](#) measurements.

Among other factors to judge the quality of a spectrograph is its transmission: for instance, it should not lose 95% of the photons reaching the telescope because of too many optical elements.

Key Research Findings

Recent developments in spectroscopic techniques have aimed at responding to new needs of the astronomer. Among them two have particularly emerged: linking imaging and spectroscopy and

simultaneous spectroscopy of a large number of objects (we do not discuss here developments in ► [radio astronomy](#) or very short wavelength astronomy).

Spectroscopy of extended objects: integral field spectroscopy. Conventional spectrographs are well adapted to stellar physics, which studies essentially spatially unresolved objects. However, when one deals with extended objects such as planets, galaxies, or some nebulae (HII regions, planetary nebulae), the access to spectral information anywhere on the object is required to understand the physics that governs the different parts (e.g., the temperature) or to measure the relative velocities, etc. A conventional spectrograph does not allow it, its entrance slit limiting the field of view.

Different ideas have been proposed to obtain what is called an integral field spectrograph that can simultaneously obtain spectra from all points of the field or at least from a significant number of cells covering the object.

One idea is to divide the field of view into small cells with an array of microlenses, each of which

will form a small bright spot at its focus. Each point feeds one optical fiber among a few tens of fibers arranged in a compact bundle. The light is then carried by each fiber to the entrance slit of a spectrograph where the output fibers are aligned along the slit. This configuration is well suited to simple objects that do not require many pixels. When this is not the case, then other solutions have been proposed. A variant of the previous configuration that uses an array of microlenses is to collimate the light at the focus of each microlens on a diffraction grating (actually a grism, a particular type of grating deposited on a prism and whose advantage is that the central wavelength is not deviated) that will give a spectrum of each micro-point source. All spectra are formed on a CCD array with a trick: the dispersive grating is rotated by a small angle with respect to the pattern of microlenses, so that no overlap occurs, as illustrated below (Fig. 6).

Multi-object spectroscopy. The need to conduct simultaneous spectroscopy of many objects in the same field has emerged with the advent of large surveys in the late 1990s.

Spectroscopy, Fig. 6 The concept of an integral field spectrograph designed by George Courtès. It forms simultaneously the spectra of different regions of an object whose image has been divided into smaller areas by an

array of microlenses. Note that the dispersion is provided by a grism whose direction of dispersion is slightly rotated relative to the pattern of microlenses so as to avoid overlapping spectra of nearby regions

Two concepts have been successfully developed: One is based on the use of a bundle of several tens of optical fibers and the other one on the use of a slit mask. In the first case, the head of each fiber is positioned very precisely in the field of the telescope, at the location, previously measured, of the object. This positioning is performed by robotic arms or by fixing each fiber head on a large metal plate thanks to a magnet. The plate is then placed at the focus of the telescope by a robotic system. The other end of each fiber is placed on the entrance slit of a standard spectrograph that can accommodate a large number of them and produces all spectra simultaneously.

In the second configuration, a mask punched with small slits at the locations of objects whose spectrum is wished is put in place at the focus of the telescope. An optical system, a grism, can then decompose the light from each of the mini-slits to form as many spectra as there are selected objects. One has to choose carefully the slit positions so that the spectra do not overlap and cover almost entirely the surface of a CCD array of large size. The punching of the masks is done by machining a thin metal plate with a power laser, after a picture was first taken from the field and then analyzed, and the objects selected by the astronomer to finally produce a code that controls the movements of the laser. The plates of planned observations are then inserted into a set of “drawers” to be set up rapidly with a great accuracy.

Spectroscopy, Electronic (UV-Vis Astronomy)

Marcelino Agúndez

Instituto de Física Fundamental, CSIC, Madrid, Spain

Definition

Electronic spectroscopy studies the electronic states of a molecule or atom and the radiative transitions between them. Each electronic state is associated with a given configuration of the electrons of the system and it is characterized by a discrete energy. The electronic spectrum is composed of lines that correspond to radiative transitions, that is, those that occur with emission or absorption of a photon, between two electronic states and usually fall in the ultraviolet and visible ranges of the electromagnetic spectrum. For more information, see, for example, the classic books of G. Herzberg (1944, 1950, 1991). Historically, UV-visible spectroscopy was the first spectroscopy used in astronomy, and it is still widely used as it permits to identify atoms in different ionization states and simple molecules like H₂ and HD, and to detect absorption from the so-called diffuse interstellar bands, presumably arising from large molecules.

Establishing, at the end of the seventeenth century, that sunlight consisted of colors which were refracted differently by prisms, Isaac Newton (1643–1727) laid the foundation of physical optics. It was only at the beginning of the nineteenth century that major experimental innovations allowed the discovery of dark lines in the solar spectrum. Kirchhoff and Bunsen's works published in 1859 gave an explanation of these lines and made the spectral analysis (soon called ► [Spectroscopy](#)) a powerful tool in the fields of astronomy, physics, and chemistry.

Overview

Spectroscopy is the study of luminous spectra, i.e., the analysis of the intensity of radiation as a function of wavelength (color, for visible wavelengths). For the Greek philosophers, such as Xenophanes (c.570–460 BCE), Aristotle (384–322 BCE), or Epicurus (341–270 BCE), the colors observed in the rainbow were only a dimming of the solar light after going through an aqueous medium denser than the air. At the beginning of the seventeenth century, Kepler took an interest in prisms, but only described the colored rays he observed at the exit of the prism, putting forward a “sensual axiom” to justify the coloration of refracted rays. In 1672, in his *Traité d'Optique* published in 1704, Newton proposed a real color theory. Newton quantified refraction for the first time, characterizing each color by a number. Indeed, Newton showed that the colors obtained with the help of the prism are homogeneous and really form the solar light.

In the eighteenth century, the Swiss mathematician Leonhard Euler (1707–1783) adhered to a wave conception of light and gave another meaning to the number connected to each color: He identified it with the wavelength in a given medium. But later on, it was on an experimental level that the study of spectra progressed. Using a slit in front of a prism, British William Hyde Wollaston (1766–1828) discovered in 1802 five dark lines in the solar spectrum; in 1815, the German optician Joseph von Fraunhofer (1787–1826) detected 576 of them by joining an astronomical reflector to the slit-prism system. The nature of these dark lines was identified by the German scientists Gustav Robert Kirchhoff (1824–1887) and Robert Wilhelm Eberhard von Bunsen (1811–1899): They arise from the absorption of light by a medium set in front of the light source. Moreover, under defined conditions of excitation, an object can only emit the radiations it is capable of absorbing. This law, called “Kirchhoff's,” allowed chemical analysis by the study of emission and absorption spectra. The Kirchhoff and Bunsen discoveries sharply affected the scientific world: e.g., spectroscopy ruined with the ideas of Auguste Comte

(1798–1857) about the impossibility of a chemical and physical study of the astronomical objects and permitted the development of astrophysics.

Spectroscopy, Rotational

Marcelino Agúndez
Instituto de Física Fundamental, CSIC, Madrid,
Spain

Definition

Rotational spectroscopy studies the radiative transitions between discrete energy levels associated

with the rotation of a molecule. Rotational level energies are related to the moments of inertia of the molecule, which in turn depend on the masses of the nuclei and the distances and angles between them. Radiative transitions between rotational states, which are only allowed for polar molecules, lead to absorption or emission of photons that usually fall in the microwave and (sub-) millimeter ranges of the electromagnetic spectrum, generally called radio in astronomy. For more information, see, for example, Herzberg (1950) and Townes and Schawlow (1975).

Spectroscopy, Vibrational

Marcelino Agúndez
Instituto de Física Fundamental, CSIC, Madrid,
Spain

Definition

Vibrational spectroscopy is concerned with the study of the vibrational states of a molecule and the radiative transitions between them. The vibrational states of a molecule are characterized by discrete energies that are related to the molecular structure via the masses of the nuclei and the strengths of the chemical bonds. Radiative

transitions between vibrational states lead to the absorption or emission of photons that usually fall in the infrared range of the electromagnetic spectrum. For more information, see, for example, the classic textbooks of Herzberg (1950, 1968).

SPECULOOS

Michaël Gillon

Astrobiology Research Unit, University of Liège, Liège, Belgium

Acronyms

SPECULOOS: Search for habitable Planets EClipping ULtra-cOOl Stars

Definition

SPECULOOS (Search for habitable Planets EClipping ULtra-cOOl Stars) is a photometric survey aiming to explore all the ultracool (M7-type and later) dwarf stars within 40 parsecs for transiting rocky planets (Burdanov et al. 2018; Delrez et al. 2018; Gillon 2018; Triaud et al. 2020). Its concept is motivated by the expected

capacity of next-generation giant telescopes to perform the detailed atmospheric characterization of potentially habitable planets at the condition that they transit a very nearby star at the bottom of the main sequence (Kaltenegger and Traub 2009; Gillon et al. 2020). SPECULOOS is based on a network of six 1 m robotic telescopes: the four telescopes of the SPECULOOS-South facility at the Cerro Paranal European Southern Observatory in Chile; the SPECULOOS-North telescope at Teide Observatory in Tenerife; and the SAINT-EX telescope at San Pedro Mártir Observatory in Mexico. SPECULOOS is a project led by the University of Liège (PI: Michaël Gillon) and carried out in partnership with the Universities of Cambridge (Co-PI: Didier Queloz), Birmingham (Co-PI: Amaury Triaud), Bern (Co-PI: Brice-Olivier Demory), and MIT (Co-PI: Julien de Wit). The scientific operations of SPECULOOS-South started in January 2019, and those of SPECULOOS-North and SAINT-EX in summer 2019. The project's prototype (Gillon et al. 2013) discovered the TRAPPIST-1 system composed of seven temperate Earth-sized planets (Gillon et al. 2016, 2017).

Definition

Spherules are distal deposits of meteorite impacts. They are spherical droplets that can form in two ways: as silicate splash particles of ejected impact melt and as condensates from the rock-vapor plume. Glassy spherules that do not contain any crystallites are called microtektites (Glass 1990). These often contain vesicles and are commonly originated as melt spherules. Crystal-bearing

spherules, in contrast, are typical to have originated from vapor condensates and are termed microkrystites (Glass and Burns 1988). Spherules can be less than a hundred micrometers to a few millimeters in diameter. Spherules may be deposited globally or in *strewn fields* which radiate from the crater.

Overview

Spherule beds are sedimentary layers that are composed entirely of spherules or, if reworked, may contain detrital material. Pure spherule beds can be up to a few decimeters thick. The impact-related origin can be recognized by geochemical anomalies that indicate extraterrestrial components, such as abnormally high concentrations of platinum group elements, especially iridium, and extraterrestrial chromium isotope signatures (Shukolyukov and Lugmair 1998, 2000), and by the presence of shocked minerals.

Spherules were first discovered by Bill Glass in 1967 in the Australasian microtektite layer which is the largest Cenozoic strewn field. Since then, spherules have been widely used to identify meteorite impacts in the Earth's and the moon's history (Chao et al. 1970). In contrast to regionally to potentially globally distributed spherule beds, craters are local features and thus more vulnerable to be entirely obliterated by erosion or tectonic processes. To date, 31 spherule layers have been identified. The Archean spherule layers in South Africa and Australia are the oldest evidence of impacts (Fig. 1) (Lowe and Byerly 1986; Lowe et al. 2003) and were formed by the largest impactors identified to date on Earth. Their bolides are thought to have been 20 km to over 100 km in diameter (Lowe et al. 1989; Melosh and Vickery 1991; Kyte et al. 1992; Shukolyukov et al. 2000). Impacts of this size had a profound effect on the environment and early life (e.g., Sleep et al. 1989; Toon et al. 1997; Naumov 2005; Pierazzo and Artemieva 2012; Kring 2003; Abramov and Mojzsis 2009). They include local effects, such as fireballs and shock waves. Large impacts may have had global effects, such as global darkening by dust loading of the atmosphere and global

Spherules,

Fig. 1 Paleoarchean spherules of the Barberton greenstone belt, South Africa

climate change. Because physical changes are relatively short lived and local, the most important biologic effects result from impact-induced environmental changes. These may cause the collapse of the food chain or the destruction of geochemical gradients. Yet, impacts may also be beneficial for life on a molecular to evolutionary scale (Cockell and Bland 2005). They are thought to potentially have carried life to Earth ($\rightarrow$ *Panspermia*) or shock-synthesized the organic building blocks necessary for life during the impact. Impacts also create new habitats such as crater lakes, hydrothermal systems, and shock-weakened rocks and can empty ecological niches to subsequently allow other species to radiate.

Definition

The Spitzer Space Telescope is the fourth of the Great Observatories that ► [NASA](#) has sent in orbit for astronomy. This three-axis stabilized pointing and scanning telescope with a spectral range from 3 to 180 μm has an 85-cm mirror made of beryllium and cooled by liquid helium (360 l at launch). The 950-kg satellite was placed on a heliocentric orbit on August 25, 2003, by a Delta II rocket launched from Cape Canaveral. Thanks to its unusual heliocentric orbit, it has continued observations with the Infrared Array Camera using only the 3.6 and 4.5 μm channels even after the cryogen was exhausted. This warm mission mode began on May 15, 2009 (Fig. 1).

History

As early as 1979, the US National Academy of Sciences was recommending a Shuttle Infrared Telescope Facility (SIRTF). The proposed 1-m telescope was supposed to operate from the Shuttle cargo bay during orbiting missions. With Shuttle weekly flights able to last up to several weeks, the telescope would be refurbished and refilled with cryogen on the ground, and focal plane instruments could be changed frequently. It appeared in 1985, after the STS-51F flight and tests of the first Shuttle-based Infrared Telescope (IRT), that the Shuttle environment would not be suitable for the IR observations. The planned observatory then changed the first word of its denomination from Shuttle to Space, still keeping the acronym SIRTF. The experience and data gained from the Infrared Astronomical Satellite (IRAS; 1983) as well the later success of the European Infrared Space Observatory (ISO, 1995–1998) led to several remodeling of the SIRTF project. During the following years, the budgetary pressure imposed a dramatic downsizing from an ambitious 5700-kg space platform

Spitzer Space Telescope, Fig. 1 NASA Spitzer Telescope (<http://www.cosmosportal.org/view/article/140793/> last accessed 31 July 2014)

to the actual 950 kg. Technical improvements saved most of the scientific objectives and performances.

Overview

The Spitzer Space Telescope is a three-axis stabilized pointing and scanning telescope with a spectral range from 3 to 180 μm . The primary 85-cm mirror is made of beryllium, and the instruments are cooled by liquid helium (360 K at launch). The 950-kg telescope was placed on a heliocentric orbit on August 25, 2003, by a Delta II rocket launched from Cape Canaveral. In this orbit, the spacecraft is trailing the Earth around the Sun, drifting away, and “losing” around 15 million kilometers per year. This orbit permits excellent,

uninterrupted viewing of a large portion of the sky without the need for Earth-avoidance maneuvers. In addition, the absence of heat input from the Earth provides a stable thermal environment. This allows innovative passive cooling of the exterior of the telescope to reach a low temperature via radiative cooling. The telescope was launched “warm” and then cooled in space for 45 days. Overall, these innovations drastically reduced the total mass of helium needed. This orbit also simplifies telescope pointing but does require the Deep Space Network for communications. The 1-m-diameter-transmitting antenna is used twice each day to transmit 12 h of stored science data.

Spitzer’s science payload consists of three cryogenically cooled instruments, which together offer observational capabilities stretching from the near to the far infrared. The Infrared Array Camera (IRAC) provides images at 3.6, 4.5, 5.8, and 8.0 μm , with two adjacent fields of view. One field of view images simultaneously at 3.6 and 5.8 μm and the other at 4.5 and 8.0 μm via dichroic beam splitters. The Infrared Spectrograph (IRS) performs both low- and high-resolution spectroscopy. Low-resolution, long-slit spectra can be obtained from 5.2 to 38.0 μm . High-resolution spectra in Echelle mode can be obtained from 9.9 to 37.2 μm . The spectrograph consists of four modules. One of the modules incorporates a peak-up function that can be used in locating and positioning sources on any of the four spectrometer slits. The Multiband Imaging Photometer for Spitzer (MIPS) is designed to provide photometry and super-resolution imaging, as well as efficient mapping capabilities, in three wavelength bands centered near 24, 70, and 160 μm .

The cryogenic mission was planned for 2.5 years and lasted actually around 5.5 years. Since May 15, 2009, after the exhausting of the liquid helium, Spitzer is on a warm mission. In this mode, only the IRAC channels at 3.6 and 4.5 μm are usable. During the cryogenic phase, the focal temperature was stabilized around 15 K, and it has been raised to 30 K during the warm phase. The mission was terminated by NASA January 30, 2020.

Spitzer Space Telescope, Fig. 2 A dragon-shaped cloud of dust seems to fly out from a bright explosion in this infrared light image taken by the Spitzer Space Telescope (*top*), a feature that is entirely cloaked in shadow when viewed in visible part of the spectrum (*bottom*). The infrared image has revealed that this dark cloud, called M17 SWex, is forming stars at a very high rate. The remnants of an older burst of star formation blew a type of bubble to the left, in the region called M17 EB. The visible-light view of the area clearly shows the bright M17 nebula, as well as the glowing hot gas filling the “bubble”

to its left. However, the M17 SWex “dragon” is hidden within dust clouds that are opaque to visible light. It takes an infrared view to catch the light from these shrouded regions and reveal the earliest stages of star formation. The *top* image is a three-color composite that shows infrared observations from two Spitzer instruments. The *bottom* visible-light image is a composite of visible-light data from the Digitized Sky Survey (DSS) from the UK Schmidt Telescope. The image combines two observations that represent the *blue* and *red* light from the region. (Image Credit NASA/JPL-Caltech/M. Povich (Penn State Univ.))

The “warm” Spitzer surveys about 700 near-Earth objects, cataloguing their individual characteristics. Such a survey is helping to gather more accurate estimates of asteroids’ compositions and sizes.

The Spitzer Space Telescope is a NASA mission managed by the Jet Propulsion Laboratory. The science and data archiving as well as the selection of observation times is managed by Spitzer Science Center, located on the campus of the California Institute of Technology and part of NASA’s Infrared Processing and Analysis Center.

Key Research Findings

Spitzer gathered a tremendous amount of data, ranging from the early universe up to extrasolar planets, including the discovery of ► [fullerenes](#) (in 2010).

With the capability of detecting stars behind dusty interstellar clouds, Spitzer snapped the first portraits of stars as they form (Fig. 2). At the same time, it was used to study dying stars, giving some insight into the possible origin of the dust filling up our Universe.

Spitzer telescope was also used to study the ultraluminous infrared galaxies (ULIRGs) emitting more than 90% of their light in the infrared. These galaxies are primarily found in the distant Universe. This large amount of infrared light could come from extreme star formation, an active central supermassive black hole, or both: three hypotheses that Spitzer could help to sort out.

Several “active galactic nuclei” (AGN) have been unveiled which were hidden from X-ray telescopes by large, massive, and dense dust clouds.

Spitzer has discovered thousands of brown dwarves and found some evidence that some of these failed stars may perhaps have planets. The large amount of such brown dwarves could also explain why galaxies are heavier than they look. Part of the “dark matter,” but not part of the exotic

undefined matter, could be represented by these dwarves that do not produce optical light and are too faint to be detected from Earth.

Some discoveries are opening wide possibilities for astrobiology, such as that terrestrial planets form around many, if not most, of the nearby sunlike stars in our galaxy, as well as around dead stars or stars as young as 1 My old.

Spitzer was the first telescope to directly detect light from planets outside of our solar system, allowing “extrasolar” planets to be directly studied and compared. The planet’s glow is extracted from the measurement of the total infrared light collected from both the star and the planet and then measuring the infrared light coming from just the star while the planet dips behind it as part of its regular orbit (see ► [Transiting Planets](#)). In this way, Spitzer identified a planetary hot spot on a hot Jupiter (Fig. 3).

Spitzer Space Telescope, Fig. 3 This plot shows the hot spot on Upsilon Andromedae B. The *black line* shows what the light curve would look like if the hot spot were in the middle of the sun-facing side of the planet. The *yellow line*

is the best fit with actual observations, demonstrating an offset of the hot spot by 80°. (Image credit: NASA/JPL-Caltech/UCLA)

Splicing

Carlos Briones

Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Synonyms

[RNA splicing](#)

Definition

In genetics and molecular biology, splicing is the process by which the transcribed RNA – also known as pre-messenger RNA – is modified to produce messenger RNA ready to be translated into proteins by the ribosomes. In eukaryotes, splicing takes place within the nucleus, after or concurrently with transcription. During splicing, introns – intervening, noncoding sequences present in split genes – are removed and degraded, and exons, protein-coding sequences, are covalently joined. This stepwise process is usually catalyzed by ribonucleoprotein complexes called spliceosomes. In turn, autocatalytic splicing is produced when certain introns are able to splice themselves out of the messenger RNA. Thus, the first ribozyme discovered was a self-splicing intron present in the precursor of the large subunit ribosomal RNA of the ciliate protozoan *Tetrahymena thermophila*.

Spontaneous Generation, History of

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Keywords

Animalcules · Origins of life

Definition

Spontaneous generations have a very long history from antiquity to the nineteenth century. From the seventeenth century, there have been three successive and important experimental approaches to this problem. From the debate between Louis Pasteur (1822–1895) and Félix Archimède Pouchet (1800–1872), the scientific community has been broadly rejecting the spontaneous generations.

Overview

The idea of spontaneous generations consists in the possibility of the formation of the living being from inert matter. This idea is extremely ancient

and comes from antiquity. For example, the Greek philosopher Aristotle (384–322 BCE) claimed that spontaneous generations existed in nature. From the seventeenth century, there have been three successive and important experimental approaches of this problem.

In 1668, the Italian naturalist Francesco Redi (1626–1697) published the results of his experiments on the possible spontaneous generation of flies. He accurately showed that the larvae of flies never developed in bottles containing meat if the former were closed by gauze. Indeed, in this case, female flies were not able to lay on meat. Therefore, Redi's results argued against the spontaneous generation of insects and visible animals.

However, the discussion carried on during the eighteenth century. For example, the French naturalist Buffon (1707–1788) claimed that spontaneous generations formed each species at the beginning of life on Earth and that spontaneous generations of animalcules occurred in nature. Consequently, according to him, after the cooling of the primitive Earth, the origin of life was the fact of spontaneous generations.

During the eighteenth century, an important scientific debate about the spontaneous generations took place. It notably opposed Joseph Needham (1713–1781) and Lazzaro Spallanzani (1729–1799). The former claimed that in his experiments he had proven the spontaneous generations of animalcules. Indeed, he had placed hot sheep juice in closed bottles and maintained them on warm ash during several minutes to purify them. A few days later, microscopic animalcules had appeared. But Spallanzani did not accept these results. He repeated the experiments, heating and closing the bottles differently, and animalcules never developed. Arguing about their results, Needham, who was an excellent microscopist, very close to Buffon, claimed that Spallanzani had destroyed the vital force because of too much heating.

The debate was not limited to a circle of naturalists and strongly interested philosophers: Denis Diderot (1713–1784) supported the spontaneous generation theory, whereas Voltaire did not.

At the beginning of the nineteenth century, the discussion about the possible existence of spontaneous generations was far from being closed. For example, the French naturalist Lamarck took a significant interest in spontaneous generations in his theory on the transformation of species.

The debate between Pouchet and Pasteur is the main and final episode of the history of this biological problem. As a supporter of spontaneous generations, Pouchet published several papers and a book on heterogenesis at the end of the 1850s. Then, in 1860, the Academy of Sciences of Paris created a contest about the experimental proofs of spontaneous generation. At the time, the debate between Pouchet and Pasteur was very active and they discussed their own protocols and experimental results. In his experiments, Pasteur showed that microorganisms appeared in sterilized solutions containing organic mixture, only if there was a contamination from the environment. In his conclusions, Pasteur firmly asserted that he had proved the inexistence of spontaneous generations. Pasteur's position on the spontaneous generations was linked to his conception of life. Indeed, according to him, the molecular dissymmetry in living beings could be the proof of an impassable frontier between inert and living bodies.

In 1862, the Academy of Sciences of Paris favored Pasteur, and from this date, the scientific community has been broadly rejecting the spontaneous generations.

Bacillus · *Clostridium* · Endospore

Definition

A small, usually single-celled asexual reproductive body produced by many nonflowering plants, ► [fungi](#), protozoans, and ► [bacteria](#) that is capable of developing into a new individual without sexual fusion.

History

For information on the early history of microbiology, including the discovery of the bacterial spore, the reader is directed to Brock (1999) and de Kruif (1926). A short history of early milestones in *Bacillus* spore research can be found in Nicholson (2004).

Overview

This entry will concentrate on bacterial spores, upon which the most information has been gathered. When faced with nutrient starvation, bacteria of several genera, most notably *Bacillus* and *Clostridium*, possess the ability to differentiate from actively growing cells into dormant resting structures called ► [endospores](#), or spores. In the context of astrobiology, bacterial spores are

important organisms to study for a number of reasons.

First, bacterial spores can persist in the environment for at least millennia and are arguably the longest-lived organisms known (reviewed in Nicholson 2004). Spores are globally distributed and are found in ► [extreme environments](#) around the world. The underlying mechanisms of why spores exhibit such incredible hardiness have been the subject of intense study for the past half-century. Spores are highly resistant to being killed by a large range of physical parameters such as extremes of temperature, radiation, or pressure, as well as by various chemical disinfectants. Some of the various mechanisms of spore resistance are quite well understood at the molecular level, such as resistance to ultraviolet radiation (reviewed in Nicholson et al. 2000, 2005; Setlow 2006). However, the molecular details of spore resistance to other lethal treatments, such as heat, pressure, or certain chemicals, are not as well understood and are the subjects of current research.

Second, because of their notorious resistance and longevity, spores have been studied as possible candidates for natural transfer of life between the planets. This theory, variously dubbed “► [panspermia](#),” “► [lithopanspermia](#),” or “transpermia,” postulates that viable microorganisms, residing within meteors ejected from a planet’s surface by large impacts, could survive a trip through space to another planet (reviewed in Nicholson et al. 2000; Nicholson 2009). Spores have been shown to inhabit the interiors of near-surface igneous rocks such as ► [granite](#) and ► [basalt](#) (the most likely candidates for launch by impact) and have been experimentally demonstrated to survive the rigors of impact-mediated launch, transfer through space, high-speed atmospheric entry, and landing (reviewed in Fajardo-Cavazos et al. 2007; Nicholson 2009).

Third, spores are important in the field of ► [planetary protection](#). By international convention, spacecraft sent on life-detection missions to other planets must meet rigorous criteria for disinfection, to avoid the risk of contaminating the target planet with Earth microbes (Rummel 2001;

reviewed in Nicholson et al. 2009). To comply with planetary protection requirements, robotic landers and rovers are assembled in ultraclean rooms inside Spacecraft Assembly Facilities (SAFs). Interestingly, precisely because of their environmental ubiquity and resistance to killing by chemical and physical disinfection procedures, bacterial spores are common isolates from the ultraclean rooms in which spacecraft are assembled and indeed from the spacecraft themselves (Venkateswaran et al. 2001, reviewed in Nicholson et al. 2009). In fact, the most resistant spore discovered to date, *Bacillus pumilus* strain SAFR-032, was isolated from a SAF (Link et al. 2004). Therefore, it appears that ultraclean SAFs act as extreme environments which select for ► survival of only the hardiest microbes, such as spores – and these are exactly the types of organisms best able to survive the journey through space (Link et al. 2004; Crawford 2005). For these reasons, spores pose a particular risk of contaminating spacecraft sent on life-detection missions to destinations such as ► Mars, Jupiter’s moon ► Europa, or Enceladus (Nicholson et al. 2009).

Future Directions

Unlike rocks transferred between planets by chance impacts, spacecrafts are (i) designed to be launched and landed gently, (ii) highly protected from space exposure during transit, and (iii) launched on trajectories with short transit times. Therefore, spores contaminating spacecraft would have a relatively high probability to survive a voyage between Earth and, say, Mars. However, in order for such “forward contamination” to be ecologically relevant, an organism transferred into a new extraterrestrial environment must be able not only to survive, but to grow and proliferate in that environment. Recent research has been conducted to understand the ability of bacterial spores to survive, germinate, and grow in extraterrestrial environments such as the surface or near-subsurface of Mars. To date, it has been found that the surface environment of Mars – characterized by intense UV and ionizing radiation, extreme cold, a CO₂-dominated low-pressure atmosphere, and a lack of liquid water and organic nutrients –

poses a formidable barrier to survival and proliferation of spore-forming bacteria and of microbes in general (Fajardo-Cavazos et al. 2008; Nicholson and Schuerger 2005; Schuerger and Nicholson 2006; Tauscher et al. 2006).

Sputtering

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Definition

Sputtering is the process in which a solid surface, as of an ► [interstellar dust](#) grain, is eroded by the impact of atoms or ions from the gas phase. Chemical sputtering occurs when the impacting particle has relatively low kinetic energy, chemical bonds are formed between it and the surface, and desorption of a newly formed molecule incorporating surface atoms occurs. Physical sputtering occurs when the impacting particle simply knocks surface atoms into the gas; this process can involve either thermal motion for high temperature gas or non-thermal impact if a solid particle and the gas have high relative velocities. Sputtering of interstellar grains commonly occurs in shocks.

Definition

The Square Kilometre Array (SKA) will be the largest radio telescope in the world for observations at centimeter and meter wavelengths. It is an international project involving more than fifteen countries, coordinated by the SKA Observatory (SKAO). The SKA is planned to be built in two phases, with the first consisting of two radio interferometers located at two sites, SKA LOW in Western Australia and SKA MID in South Africa. Construction activities began in 2021 and are expected to be completed toward the end of the decade. The SKA will deliver transformational science in a number of astronomy and physics fields, including astrobiology as described below.

History

The original concept that would later evolve into the SKA began formulating in the late 1980s and was led by a group from the Netherlands. This idea was discussed with members of the UK astronomy community in 1990 at the 10th anniversary meeting of the Very Large Array, and in 1993 the International Union of Radio Science (URSI) established the Large Telescope Working Group to develop the scientific goals and technical specifications for a next generation radio observatory. In 1997, eight institutions from six countries (Australia, Canada, China, India, the Netherlands, and the USA) signed a Memorandum of Agreement to cooperate in a technology study. The number of countries increased to 11 during 1999 for the creation of the International Square Kilometre Array Steering Committee (ISSC). In 2007, an international SKA Project Office was established in the UK. The Square Kilometre Array Organisation (SKAO) was then established in 2011 as a nonprofit company in the UK to formalize relationships between the international partners and to centralize the leadership of the project. In 2012, it was agreed that phase 1 of the SKA should be built on two sites in Western Australia and South Africa, both chosen for their remarkable radio quietness. In 2015, a cost

reduction exercise scaled back the number of telescopes from three to two, and the design work would continue focusing on SKA LOW in Australia and SKA MID in South Africa. The design phase formally concluded in 2020, and in 2021 the SKA organization transitioned into an intergovernmental organization with the birth of the SKA Observatory. The main SKAO office is located at the Jodrell Bank Observatory south of Manchester, UK. As of July 2021, there are seven member countries who have ratified the SKAO treaty to become formal members, with an additional six partner countries.

Overview

SKA1 construction activities formally began in July 2021 and are expected to last for 7 or 8 years. The design baseline for SKA LOW consists of 512 stations, each containing 256 log periodic dipole antennas operating within the frequency range of 50 to 350 MHz. The maximum separation between these stations will be approximately 65 km. In the case of SKA MID, the existing 64 antenna MeerKAT array will be combined with 133 15 m diameter dishes equipped with single-pixel feed receivers operating between 350 MHz and 15 GHz. The maximum separation between SKA MID dishes will extend out to 150 km. Signals between stations or antennas will be correlated by the central signal processors, located at the Murchison Radio Observatory (MRO) in the case of SKA LOW, and in Cape Town for SKA MID. The engineering teams will be located at centers in Geraldton, Western Australia, and in Carnarvon, Northern Cape.

SKA science operations centers are being established in both Perth and Cape Town, which will also be the sites of the high-performance computing facilities hosting the science data processors (SDPs). A SDP will produce nearly science-ready data products that will be distributed to the SKA regional centers (SRCs) for advanced processing. These SRCs will serve as the interface between the observatory and the broader scientific community.

Applications

The topic of Cradle of Life/Astrobiology represents one of the main SKA science drivers. The SKA will contribute to the field of astrobiology by performing sensitive and broadband spectroscopic surveys to discover unknown complex organic molecules of prebiotic interest in space. Prebiotic molecules are defined as molecular species believed to be involved in the origin of life. Precursors of proteins, lipids, nucleotides, and sugars are considered as prebiotic molecules. Among them, one may find glycine and alanine (the simplest amino acids), butanol and butanoic acid (amphiphilic molecules precursors of fatty alcohols and fatty acids, proposed to be prebiotic lipids; Ruiz-Mirazo et al. 2014), hydroxylamine or urea (precursors of ribonucleotides; Becker et al. 2019), and glyceraldehyde, erythrose, or ribose (the simplest sugars; Patel et al. 2015). Some prebiotic scenarios for the origin of life contemplate the possibility that these precursors formed in space and were brought to a primitive Earth through the impact of meteorites and comets during the period of the Late Heavy Bombardment (life emerged soon after, at about 3.8 billion years ago). Prebiotic molecules such as urea, glycine, and ribose have indeed been detected in meteorites and comets (Pizzarello 2006; Altwegg et al. 2017; Furukawa et al. 2019), which supports this hypothesis. The SKA will investigate whether the chemistry found in space (especially in the medium between stars or interstellar medium) efficiently forms prebiotic molecules, to be later on incorporated into planetesimals during the formation of solar-type systems.

Prebiotic species are discovered in interstellar space thanks to observations of their rotational spectra with radio telescopes. These species are large in size, and therefore their rotational line spectra appear shifted toward centimeter wavelengths as opposed to lighter, smaller molecules, whose rotational spectra are shifted to millimeter and submillimeter wavelengths. The SKA capabilities are therefore perfectly suited for the search for interstellar prebiotic molecules. Observations at the highest frequencies of SKA MID (with the Band 5 receivers, between 4.8 and 15 GHz) have

the potential to discover unknown prebiotic species, especially under the coldest excitation conditions of interstellar space. This potential has recently been demonstrated by deep spectroscopic surveys carried out at 3 cm and 7 mm with SKA precursors such as the Green Bank Telescope and the Yebes 40 m telescope, which have discovered a plethora of large molecules such as ethanolamine (a prebiotic species that represents the simplest head group of phospholipids; see Rivilla et al. 2021) and small polycyclic aromatic hydrocarbons (Cernicharo et al. 2021; McGuire et al. 2021).

Future Directions

The second phase of the SKA is not yet defined but may consist of an order of magnitude increase in survey speed and angular resolution. This is likely to incorporate new technologies such as a wide field of view-phased array feeds, or wide-band receivers. The possible extension of SKA MID to higher frequencies (e.g., Conway et al. 2020) would increase the detection capabilities of the SKA for the search of prebiotic species in interstellar space.

Definition

The Space Studies Board (SSB) is a unit of the US National Research Council. The original charter of the Space Science Board was established in June 1958. The Space Science Board became in 1989 the Space Studies Board (SSB) and provided expert external and independent scientific and programmatic advice on a continuous basis from NASA's inception until the present. Today, the SSB is providing an independent, authoritative forum for information and advice on all aspects of space science and applications. The SSB also serves as the US National Committee for the Committee on Space Research (COSPAR) of the International Council for Science.

The Board is composed of prominent scientists, engineers, industrialists, scholars, and policy experts in space research appointed for 2-year staggered terms. The Board itself does not

conduct studies, but it oversees advisory studies and program assessments conducted by ad hoc study committees formed in response to a request from a sponsor. It publishes the reports of such studies. Decadal surveys are a major outcome from the SSB, providing strategic direction to NASA and other agencies on the top priorities over the next 10 years in astronomy and astrophysics, solar system exploration, solar and space physics, and Earth science.

Concerning astrobiology, the SSB has issued numerous reports in addition to the decadal surveys – about ► [Mars exploration](#), ► [planetary protection](#), and mission categorization. Special focus was given to the ► [Mars sample return mission](#).

France

Keywords

Isotopes · Isotope fractionation · Fractionation factor · Stable isotopes · Nontraditional

Definition

The term isotope defines the various forms of a chemical element, characterized by the same number of protons but different numbers of neutrons in their nucleus. Isotopes share the same atomic number and location in the periodic table, but have distinct atomic weights. Two types of isotopes can be distinguished: radioactive or stable. Stable isotopes of a single element have roughly identical properties due to similar electronic configuration and atomic size, but their mass differences induce variations in terms of bound energy and chemical reactivity. In a specific process, stable isotopes are thus fractionated according to either equilibrium or kinetic reactions.

History

Stable isotope geochemistry was born around 1945, and its first application was dedicated to geothermometry (Urey 1947). Experimental applications were initiated by McCrea (1950) and illustrated by the early work of Urey et al. (1951) on ambient paleotemperatures of the Upper Cretaceous in the northern hemisphere, measuring oxygen isotopes in carbonates. Since then the development of stable isotope geochemistry has been rapid and exponential, with applications to all kinds of geological and extraterrestrial environments.

Overview

Stable isotopes in natural environments have been identified for 81 elements, from hydrogen to lead. Contrasting with radioactive isotopes, which are mostly used for dating or deciphering mixing processes, stable isotopes can be applied to trace any type of physicochemical reaction such as diffusion, dissolution/precipitation, oxidation/reduction, acid/base exchange, evaporation/condensation, or adsorption. Stable isotopes can be useful to distinguish biotic from abiotic signatures recorded in ancient terrestrial rocks or meteorites.

For extensive reviews on stable isotopes and their use in geochemistry, the reader should refer to textbooks such as Criss (1999) and Hoefs (2004).

Stable isotopes are presently classified as either “traditional” or “nontraditional.” Traditional stable isotopes refer to isotopic tracers developed since the earliest works in the 1950s and include systems such as C, O, H, N, or S. A common feature of these traditional stable isotopes is the analytical method based largely on gaseous Isotope Ratio Mass Spectrometry (IRMS). For instance, C and N isotope compositions are measured on the molecules CO₂ and N₂, respectively. Nontraditional stable isotopes refer to isotopic systems developed more recently (since the 1990s) and include heavy metals such as Fe, Cu, Zn, Cr, Se, and Mo and alkali or alkaline earth metals such as Li, Mg, and Ca. These elements are usually separated from sample matrix using aqueous chemistry and chromatographic methods. Isotope analyses are performed either on solid using thermo-ionization mass spectrometry (TIMS) or aqueous solution using multicollector inductively coupled plasma mass spectrometry (MC-ICPMS). It is likely that nontraditional stable isotopes may become traditional in the next few decades, and this term may need to be revised. Recent reviews on traditional and nontraditional stable isotopes have been published in volumes of Reviews in Mineralogy and Geochemistry (Valley and Cole 2001; Johnson et al. 2004).

Basic Methodology

Stable isotope compositions are generally reported in δ notation, which is a deviation of an isotopic ratio relative to the same ratio in a standard, and can be written as

$$\delta^i E = \left(\frac{R_{spl}^{i/j} - R_{std}^{i/j}}{R_{std}^{i/j}} \right) \times 10^3$$

where R is the ratio of the two stable isotopes i and j of element E , spl is the sample of interest, and std is the standard reference material. The δ unit is expressed in parts per thousand or “per mil,” noted ‰. The ratio i/j usually corresponds to

heavy over light isotopes so that positive δ value indicates that the sample is enriched in heavy isotope relative to the standard (and vice versa). A careful examination of the standard material is thus crucial when considering δ values. For traditional stable isotopes, the standards are well established. For instance, carbon stable isotope composition (ratio $^{13}\text{C}/^{12}\text{C}$) is always expressed as $\delta^{13}\text{C}$ relative to the fossil marine carbonate standard (PDB), while the standard for hydrogen isotope composition (D/H ratio) is Standard Mean Ocean Water (SMOW). In contrast, for recent “nontraditional” stable isotopes, data from the literature are sometimes reported relative to various standards (e.g., igneous rock or IRMM-014 synthetic metal for Fe isotope composition, see Craddock and Dauphas (2010)).

Isotope fractionations between species or phases can be determined experimentally or predicted from theoretical calculation (e.g., Richet et al. 1977). The isotopic fractionation factor associated to an isotope exchange reaction between two species A and B is defined as:

$$\alpha_{A-B} = \frac{R_A^{i/j}}{R_B^{i/j}}$$

and can be expressed in terms of δ values as

$$\alpha_{A-B} = \frac{1,000 + \delta^i E_A}{1,000 + \delta^i E_B}$$

The isotope fractionation between two species A and B represents the difference between their isotope compositions and can be related to the fractionation factor using the following formulae (e.g., Criss 1999):

$$\Delta_{A-B} = \delta^i E_A - \delta^i E_B \approx 1,000 \cdot \ln \alpha_{A-B}$$

Applications

Stable Isotopes in Astrobiology

The main questions in astrobiology concern the origin and evolution of life on Earth and whether life may have risen elsewhere in the Solar System and on extrasolar planets. Stable isotopes are powerful tools for tracing microbial processes and the

origin of biomolecules in various geological and extraterrestrial systems. Applications range from direct analyses of organic components to identification of biominerals, formed through biological-induced (extracellular) or biological-controlled (intracellular) pathways. One of the key observations is that traditional stable isotope systems such as C, H, N, O, and S all represent the basic components of life. This was recognized very early in studies of stable isotope geochemistry, so that these systems were rapidly used for searching for life signatures in the geological record. The most famous system is probably C isotopes, and one of its well-known applications can be summarized as follows. Inorganic carbon assimilation by autotrophic organisms is based on various carboxylation pathways with specific kinetic isotope fractionations, favoring light isotope assimilation. Organic carbon is thus ^{12}C enriched relative to the source of inorganic carbon (DIC: dissolved inorganic carbon), with an isotopic fractionation $\Delta^{13}\text{C}_{\text{DIC-Corg}}$ generally between -20‰ and -30‰ (see review in Thomazo et al. 2009). In contrast, carbonate precipitation from dissolved inorganic carbon roughly records the composition of the source (i.e., the equilibrium isotope fractionation is $\sim 1\text{‰}$). The difference of isotope compositions between carbonate and organic carbon coexisting within a single rock sample can thus be used to determine if organic carbon is related to biological activity or not and eventually define the C assimilation pathway. This feature was recognized in the 1970s and has been used to infer the existence of life on Earth as early as 3.8 Ga ago (Schidlowski 1988). The virtue of stable isotopes for life identification is that even though a rock experienced strong modifications of structure and mineralogy due to metamorphism, the primary isotope signature may be preserved.

A Reliable Biosignature?

An important limit on the application of stable isotopes as tracers of life is that abiotic processes may mimic isotope fractionations usually ascribed to biogenic origin. For instance, several experimental studies demonstrated that the production of organic carbon through abiotic pathways such as ► [Fischer-Tropsch-Type Reaction](#) generates C isotope compositions similar to those expected

for biological pathways. Thus the question of the origin of ► [methane](#) on Mars and Titan (which has been suggested to derive from bacterial methanogenesis or abiotic ► [serpentinization](#) process) will probably not be solved from C isotopes alone. One possibility to explore further may be the simultaneous measurement of C and H isotopes in methane and other types of hydrocarbons (Sherwood Lollar et al. 2002).

Sulfur isotope composition recorded in ancient sedimentary sulfides may represent one of the most reliable isotopic biomarkers, with no abiotic counterpart. Indeed, bacterial sulfate reduction (BSR) produces a strong kinetic isotope fractionation, favoring the light S isotopes in the hydrogen sulfide product by $\sim 45\text{‰}$ in terms of $^{34}\text{S}/^{32}\text{S}$ ratio (see the pioneer work by Harrison and Thode 1958). When aqueous Fe^{2+} is present, hydrogen sulfide immediately precipitates as FeS and is then transformed into pyrite (FeS_2). Watanabe et al. (2009) showed experimentally that abiotic thermochemical sulfate reduction produces hydrogen sulfide either enriched or depleted in light S isotopes, with a range of $\Delta^{34}\text{S}_{\text{SO}_4\text{-H}_2\text{S}}$ from -20‰ to $+5\text{‰}$. The record of very negative $\delta^{34}\text{S}$ values in pyrite thus remains an unchallenged tracer of bacterial sulfate-reduction activity. The main drawback of this method is that the expression of the isotope fractionation depends strongly on the size of the sulfate reservoir. At low sulfate concentrations, the uptake and reduction of sulfate by microorganisms does not result in significant discrimination between sulfur isotopes and, therefore, does not produce significant fractionations. In contrast, at high sulfate concentration, large isotope fractionation can be efficiently transferred to sedimentary sulfides. Based on this interpretation, the long-term evolution of the sulfur isotope record on terrestrial sediments has been interpreted to reflect the response of sulfate-reducing bacteria to changes in oceanic sulfate concentrations (Canfield et al. 2000).

Future Directions

The identification of biological activity from a single isotope system is limited by the possibility of producing similar isotope fractionation from abiotic reactions. Unequivocal evidence for life

will require the combination of several isotope tracers (C and H in methane, S and Fe in iron sulfides, Fe and O in iron oxides, Ca, Mg, Fe, C, and O in carbonates. . .). Additionally, a coupling with other methods such as mineralogy (shape, size, crystallinity) or chemistry (e.g., purity) will put further constraints on potential biological origin as exemplified by multidisciplinary study of the Martian meteorite ► [ALH 84001](#) (McKay et al. 1996). A promising field, which grows with improvement of the analytical precision on stable isotope measurements, is the analysis of multiple-isotope systems for elements that possess three or more isotopes (e.g., O, S). Once calibrated, application of these systems may provide useful tools for distinguishing biological from abiotic pathways (Farquhar et al. 2003).

Stagnant Lid Convection

Doris Breuer

German Aerospace Center (DLR), Institute of Planetary Research, Berlin, Germany

Definition

Stagnant lid convection is a form of convection that occurs in a material with strongly temperature dependent viscosity for a viscosity contrast larger than about 10^4 . It is characterized by an upper stagnant layer – the stagnant lid – that

forms on top of the convecting layer. Heat in the stagnant lid is transported mainly by heat conduction. Stagnant lid convection is typical of ► [mantles](#) of the ► [terrestrial planets](#), ► [Mercury](#), ► [Mars](#) and ► [Venus](#) and large rocky satellites such as the Moon. Stagnant lid convection may also occur in the ice layers of the icy satellites of the outer ► [Solar System](#). Stagnant lid planets are usually also one-plate planets. Their tectonic style differs substantially from planets with mobile lid convection or ► [plate tectonics](#) like Earth. Here, the near-surface layers take part in the convective flow and are recycled with the interior.

Keywords

Infrared spectroscopy · Evolved stars · Stellar winds

Synonyms

[Circumstellar grains](#)

History

The fact that stars can manufacture solid-state particles in large quantities (stardust) was first recognized through the discovery of infrared excess in the spectra of evolved stars. Infrared spectrophotometric observations in the late 1960s have revealed that stars in the ► [asymptotic giant branch](#) (AGB) of evolution show excess emission above the stellar photospheric continuum emission (Woolf and Ney 1969). This excess is interpreted as the result of thermal emission by micron-size solid particles (grains) heated by the stellar radiation. These solid particles absorb visible light from the star and reemit the energy in the infrared.

Overview

Stardust also manifests itself through the absorption of starlight. Circumstellar dust can cause very large extinction in the visible. In extreme cases, the entire photospheric output of a star is converted to dust emission, making the star itself extremely faint or even invisible in optical light (Volk et al. 1992). The most well-known examples of such stars are IRC + 10216 and AFGL 3068, which are very bright in the infrared but very faint in the visible.

In terms of chemical composition, stardust can be either oxygen rich or carbon rich. The most common kinds of oxygen-rich solid particles are

amorphous silicates, which manifest themselves through their Si–O stretching mode at 9.7 μm and the Si–O–Si bending mode at 18 μm . In the *Infrared Astronomical Satellite* ($\blacktriangleright$ [IRAS](#)) low-resolution spectrometer (LRS) all-sky survey, over 4000 oxygen-rich AGB stars were found (Fig. 1). The most common kind of carbon-rich stardust is silicon carbide, which is detected in over 700 carbon-rich AGB stars (Kwok et al. [1997](#)).

In addition to amorphous silicates and silicon carbide, silicate minerals (olivines and pyroxenes) as well as several refractory oxides are also made in the circumstellar envelopes of AGB stars. A broad feature centered around 13 μm , first discovered by the IRAS LRS, could be due to corundum ($\alpha\text{-Al}_2\text{O}_3$, which has a feature at 12.7 μm), glass (amorphous SiO_2 , 12.3 μm), spinel ($\text{Mg}_2\text{Al}_2\text{O}_4$, 12.95 μm), or rutile (TiO_2 ,

Star Dust, Fig. 1 Infrared spectra of amorphous silicates. The 9.7 and 18 μm features of silicates can be seen both in emission (*top panel*) and in self-absorption (*bottom panel*). (Data obtained from the low-resolution spectrometer observations from the $\blacktriangleright$ [Infrared Astronomical Satellite](#))

13.4 μm). An emission feature at 19.5 μm observed by ► [ISO](#) has been attributed to a mixture of Mg-Fe-oxides (e.g., $\text{Mg}_{0.1}\text{Fe}_{0.9}\text{O}$) (Posch et al. 1999, 2002). The detection of minerals in stellar environments has led to the establishment of the field of astromineralogy (Henning 2003).

Stardust of organic composition has also been found in carbon-rich ► [planetary nebulae](#). Organic stardust has not been detected in AGB stars, suggesting that these particles are synthesized in the post-AGB phase of evolution, after the synthesis of gas phase molecules such as acetylene and benzene (Kwok 2004).

Stardust can also be found in the vicinity of young stars, Wolf-Rayet stars, planetary nebulae, novae, and supernovae. The disc shape of the dust-emitting region around young stars is suggested to be the precursor of the nebula out of which planets form.

The exact mechanism of stardust formation is not known. It is usually assumed that these solid particles are the result of ► [nucleation](#) through collision of gas-phase molecules. When the particles are far enough from the stellar surface such that the radiation temperature of the particles has fallen below the condensation temperature of the solid, it will condense spontaneously, similar to soot formation in a flame. Spectral monitoring of novae has shown that novae change from a gaseous free-free spectrum to a dust thermal emission spectrum over periods as short as a few days, suggesting that dust can condense in novae ejecta very quickly (Ney and Hatfield 1978).

Stardust is generally believed to be the source of solid-state particles found in the interstellar medium (► [interstellar grains](#)). Through radiative and physical processes, the morphology and/or chemical composition of stardust may be modified in the interstellar medium. Most interestingly, various presolar grains (SiC, diamonds, corundum, silicates) of stellar origin have been found in meteorites, suggesting that we actually can hold stardust in our hands (Zinner 1998). The presence of stardust in the solar system provides evidence that stardust is sturdy enough to survive its journey through the ► [interstellar medium](#).

Star Formation Rate

Daniele Galli
INAF Osservatorio Astrofisico di Arcetri,
Florence, Italy

Acronyms

SFR

Definition

The star formation rate (SFR) is the mass of stars formed per unit time in galaxies or in star-forming regions within galaxies. It is usually measured in solar masses per year ($M_{\odot} \text{ yr}^{-1}$), or in solar masses per year per square parsec ($M_{\odot} \text{ yr}^{-1} \text{ pc}^{-2}$). Currently, the SFR in our Galaxy is about $4 M_{\odot} \text{ yr}^{-1}$. Methods for estimating the present-day SFR in galaxies are generally based on measuring the emission of tracers of the young stellar population, for example, *high-mass stars* and *supernovae*. The SFR is one of the key ingredients in models of galactic chemical evolution. A related concept is the star formation history (SFH), the time evolution of the star formation rate. Suggested readings: Kennicutt and Evans (2012), Krumholz (2014).

Star Formation, Feedback

Mark Krumholz
Research School of Astronomy and Astrophysics,
Australian National University, Canberra, ACT,
Australia

Definition

Star formation feedback refers to the collection of processes by which newly formed stars alter the

interstellar gas from which they form, or alter their interstellar environment more broadly. These processes include radiative heating, photodissociation, and photoionization, and acceleration and shocking by stellar outflows, winds, and supernova explosions. In most cases, feedback inhibits further star formation or disperses the star-forming interstellar clouds, reducing the overall star formation rate in the region. In some special circumstances, however, feedback processes can also accelerate star formation locally; this is known as positive feedback or star formation triggering.

History

While many of the individual processes involved in feedback have been known since the early- to mid-twentieth century, the study of star formation feedback as a collective phenomenon has two main roots, one Galactic and one extragalactic. Zuckerman and Evans (1974) and Scoville and Solomon (1975) pointed out that if the molecular clouds in the Galaxy were all collapsing freely into stars, the resulting rate of star formation would greatly exceed the observed rate. They suggested that the large velocities detected in molecular clouds via Doppler measurements must therefore represent turbulent motions rather than collapse and suggested that feedback might be responsible from driving the turbulence and inhibiting collapse. On the extragalactic side, Larson (1974) and Dekel and Silk (1986) suggested that the observed lack of star formation in elliptical galaxies and the low surface brightness and metal content of dwarf galaxies, respectively, could only be explained if these galaxies were to lose a substantial fraction of their interstellar gas and metals to the intergalactic medium. They argued that ejection of gas from the galaxy by supernova feedback was likely responsible for this loss.

Definition

Star formation is the process by which denser regions of interstellar ► [molecular clouds](#) fragment and collapse into smaller cores that become hot enough at the center to initiate the process of nuclear fusion, thereby creating a star. Observations of star formation require all wavelengths from radio to X-ray and help elucidate the

processes underlying the birth of both low-mass and high-mass stars.

History

It is worth reviewing a little bit of the history behind the realization that star formation is an ongoing process in our Galaxy. By the middle of the twentieth century, the theory of stellar structure and evolution had already demonstrated that the hottest stars (OB stars) consume their nuclear fuel at such a prodigious rate that they can live for only a short fraction of the lifetime of our Galaxy. So the very fact of their continued existence was proof that star formation has occurred in the present epoch of galactic history. In addition, in the 1940s, the Armenian astronomer Viktor Ambartsumian showed that OB stars are in associations (see “► [OB Association](#)”) whose internal motions would cause them to be disrupted on timescales in agreement with the nuclear ages of the individual stars in the association (that is, on times much less than the age of the Galaxy), again providing direct observational evidence that star formation is still ongoing in our Galaxy. The last piece of the puzzle was provided by the discovery of the ► [interstellar medium](#) (ISM) of gas and dust in the early part of the twentieth century. Observations of the ISM established that the clouds of interstellar material (giant molecular clouds) had roughly stellar chemical composition, but were much more massive than individual stars or stellar associations. The presence of the ISM showed that the raw material needed to make stars was relatively abundant in the Galaxy.

For many years, direct observations of the star formation process, and subsequent development of a good theory, have been hampered severely by the fact that the earliest phases of star formation occur in dark clouds which have an extremely large amount of extinction toward them, rendering them optically opaque. Fortunately, over the past 40 years, significant advances in infrared to millimeter wavelength technologies have spurred progress in a new generation of ground and space telescopes and associated instrumentation that has allowed to trace the cold ISM material and to

study in detail even the most deeply embedded stages of star formation. Important milestones in the star formation field from an observational point of view include: the first all-sky infrared images provided by the ► [Infrared Astronomical Satellite](#) (IRAS) space telescope, launched in 1983, which identified the coldest regions in the ISM; the spectral classification of embedded young infrared sources in different evolutionary classes depending on the shape of their spectral energy distribution, which is related to the amount and distribution of the surrounding dust and its temperature (Lada and Wilking 1984; Lada 1987); the discovery of collimated optical and infrared jets and of bipolar molecular outflows traced by high-velocity CO emission; the spectacular optical and infrared view of star-forming regions provided by Hubble since its launch in 1990; the first images of the dust continuum emission from the youngest protostars in the 1990s; the Infrared Space Observatory (ISO) discovery of water and other important molecules in the ISM; Spitzer space telescope systematic imaging in the near- and mid-infrared for a complete census of protostellar populations in the 2000s; the ubiquitous presence of filaments in the ISM revealed by the Herschel Space Observatory in 2010s, where most of the star formation in the Milky Way is taking place; and since 2011, the multiple results obtained with ALMA, including the stunning images of protoplanetary disks with rings, gaps, and spirals.

Overview

The theory of ► [stellar evolution](#), which has been very successful in explaining the life history and the death of stars, has nevertheless been unable to explain how stars form. It is likely that the inherent complexity of the physical processes behind star formation is the main reason for this inability of the theory. Knowledge of the physical mechanisms that govern the formation of stars within molecular clouds is crucial, as it has a wide-ranging impact on a variety of other fields of astronomy. Thus, understanding star formation is necessary to form a clear picture of galactic

evolution from the Big Bang to the current time in cosmic history. The development of a theory of star formation (see “► [Star Formation, Theory](#)”) is also important for the study of the origin of planetary systems, which in turn has implications for biology outside the solar system (see “► [Protostars](#)”).

The fact that star formation is an ongoing and continuous process that extends from the early universe into the present epoch is an important property of the universe. This facilitates the study of star formation because it allows us to investigate the physical processes of various stages of star formation with observational methods.

Basic Methodology

We know from observations that the dark patches that can be seen crossing the Milky Way in the night sky are not devoid of material. They are made up of many interstellar dark clouds which contain gas and tiny opaque dust grains that effectively absorb and scatter starlight (see “► [Interstellar Dust](#)”). These dark clouds are the sites of star and planet formation in the Galaxy. The first millimeter-wavelength observations in the 1970s showed that these dark clouds are predominantly molecular in composition (see “► [Molecular Cloud](#)”) and with a temperature of 10–15 K are some of the coldest objects in the universe. The observations that were performed were molecular line surveys of carbon monoxide, CO. While cold molecular hydrogen has no detectable emission spectrum, CO is the next most abundant molecular species after H₂ in these regions and is easily detected at millimeter wavelengths. CO observations show that the molecular mass of the Galaxy is about two billion solar masses and that this mass is concentrated tightly in the flattened galactic disk and is dominated by giant molecular clouds (GMCs). The physical properties of GMCs are reviewed exhaustively in many papers (see, e.g., Evans 1999). With sizes ranging from 20 to 100 pc, and masses ranging from 10⁴ to 10⁶ M_☉ (solar masses), these objects are the largest structures in the Milky Way and rival ► [globular clusters](#) for sheer mass. The mean densities of

GMCs are $50\text{--}100\text{ molecules cm}^{-3}$ which, given their cold temperatures, implies that they are gravitationally bound, if not stable entities (see “► [Jeans Criterion](#)”). Measurements of molecular line widths indicate cloud velocity dispersions of $2\text{--}3\text{ km s}^{-1}$. Given the cloud sound speed $c_s \sim 0.2\text{ km s}^{-1}$, the velocity fields of these objects are highly supersonic. These supersonic motions are not for the most part due to systematic motions such as collapse or expansion, but appear to be turbulent in nature. For example, the relation between molecular line width and cloud size is similar to that expected for incompressible turbulent flows (Larson 1981). The lifetime of typical GMCs is an area of considerable controversy, with estimates ranging from an order of the free-fall time of the GMC (a few million years) to as much as 100 million years. Clearly it is important to have a better constraint on the ages of these complexes to understand the evolution of such clouds into stars.

Within GMCs, there are identifiable discrete entities with higher densities. These are referred to as dense cores, have typical sizes ranging from 0.1 to 1 pc, and typical mean densities of $10^4\text{ molecules cm}^{-3}$, with central densities reaching up to 10^6 cm^{-3} . The fraction of GMC mass in these dense cores is typically 1–10%, with the most evolved GMCs having higher percentages. The masses of these dense cores vary from 1 to $1000\text{ M}_\odot$. The frequency distribution of the masses tends to follow a power law, such that most of the mass in dense molecular gas is located in $M \geq 100\text{ M}_\odot$ cores. The velocity dispersions of dense cores tend to be supersonic, with the low-mass cores tending to have smaller dispersions, which in some cases become subsonic. Higher-mass cores tend to be warmer and more turbulent.

The mass distribution of dense cores in star-forming regions, the so-called core mass function (CMF), would be the precursor of the stellar initial mass function (IMF), which describes the distribution of masses for a population of stars (see “► [Initial Mass Function, Origin of](#)”). The IMF can be well described by a power law of the type $dN/dM \propto M^{-\alpha}$ for masses above about a solar mass, with $\alpha = 2.35$, the well-known Salpeter IMF (Salpeter 1955). Knowledge of the CMF

and of the content and distribution of ► [protostars](#) and young stellar objects (YSOs) within the GMCs or any molecular cloud is important for understanding how the process of star formation proceeds within it. Since protostars are often buried deep within the clouds, they tend to be invisible optically. However, the opacity of dust is an order of magnitude smaller in these sites at longer wavelengths compared to optical wavelengths. The younger or less evolved the star is, the more heavily obscured it typically is, and for such objects, far-infrared and submillimeter observations are required to study them.

The initial conditions and the earliest stages of star formation in dense cores are still areas of active study for observers and theorists. In active star-forming clouds such as those in Orion and Taurus, a large fraction of dense molecular cores harbor stars, while in clouds with a low level of star formation, 75% of the dense cores are starless (Lee and Myers 1999). Starless and prestellar cores offer a unique opportunity to constrain the initial conditions of star formation. Submillimeter observations of the dust emission from prestellar cores show that these cores have densities that are not strong functions of cloud radius, unlike cores with stars. It is also interesting to note that the measured emission line widths of starless cores are consistent with purely thermal internal motions and do not show any evidence of turbulent broadening. This may indicate that dense cores form initially from turbulent cores, but evolve by dissipating the internal turbulence before forming stars. Interestingly, observations of gravitationally bound prestellar cores indicate that the CMF of these cores is similar to the ► [initial mass function](#) (IMF) of Galactic field stars. This suggests that the origin of the initial distribution of stellar masses could be the CMF.

At least in isolated, low-mass dense cores, the formation of stars from dense cores is now well understood and backed with a wealth of observations and a good theoretical underpinning (see e.g., Shu et al. 1987; Larson 2003). The theoretical process can be described as follows: Before being incorporated into a forming star, the molecular material within the collapsing dense core must increase in density by 20 orders of

magnitude and decrease in size by 7 orders of magnitude relative to its initial state. Because the dust in the material is optically thin, internal energy and heat generated by collapse is radiated away, thereby maintaining the same temperature in the core. The collapse thus proceeds in an isothermal, dynamical manner, with the inner layers becoming denser and collapsing faster than the outer layers which are left behind. Eventually the inner layers become dense enough to become optically thick to their own radiation, resulting in the formation of a quasi-static stellar core surrounded by an infalling envelope. Magnetic fields, together with turbulence, may play a role in the whole process of star formation. Indeed, according to Shu et al. (1987), magnetic fields could be strong enough to be responsible for the low rate of star formation in the Milky Way (see “► [Magnetic fields and Star Formation](#)”). The morphology and strength of the magnetic field in star-forming regions can be estimated from dust polarized observations, assuming that the polarization pattern is due to dust grains with their shortest axis parallel to the magnetic field, and Zeeman splitting of suitable molecular lines.

Key Research Findings

Giant Molecular Clouds and Dense Cores

The IRAS space telescope in the early 1980s produced the first sensitive surveys in the mid- to far-infrared emission of GMCs. By the end of that same decade, near-infrared imaging detectors mounted on ground-based telescopes added complementary data. In the late 1980s and 1990s, the IRAS observations were followed up with targeted millimeter and submillimeter observations of star-forming regions. Large-scale CO surveys of molecular clouds revealed the vast extent of CO in the Galaxy and allowed us to study not only the physical properties but also the kinematics of GMCs (e.g., see Dame et al. 1987; Jackson et al. 2006; Schuller et al. 2017). All these competing but complementary surveys revealed that (1) stars form in dense molecular gas ($\geq 10^4$ H₂ molecules cm⁻³), (2) most stars form in embedded clusters, and (3) the overall efficiency of star

formation in GMCs is quite low (1–3% or less). The low global star formation efficiency is rather significant. This indicates that the bulk of the molecular mass in GMCs does not participate in the star formation process and exists in a semi-stable configuration. In this sense, the problem of star formation shifts from finding what makes the bulk of the material collapse to finding what holds up the bulk of the material against global collapse (see Shu et al. 1987). Molecular emission line and extinction surveys do find that a small fraction of molecular gas is at high density, and, not surprisingly, the efficiency of star formation in dense cores is much higher (10–20%) compared to the efficiency in the entire GMC. The highest efficiencies are found in the most massive cores that form embedded clusters (e.g., Lada 1992). At the turn of the millennium, a large number of ground-based near-infrared surveys combined with space telescope observations such as Hubble Space Telescope, Spitzer Space Telescope, and Herschel Telescope were used to study dense cores. Herschel Telescope observations of the ISM revealed the ubiquitous presence of complex networks of filamentary structures within interstellar clouds (see “► [Interstellar filaments](#)”) that play a crucial role in the star-forming process (see, e.g., André et al. 2010; Molinari et al. 2010). Indeed, dust continuum observations of filaments in nearby clouds have shown that prestellar cores preferentially form in the densest filaments, which suggests that the formation of dense cores would be the result of the fragmentation and gravitational collapse of such filaments.

From Dense Cores to Stars

In the last two decades of the twentieth century, evidence of this so-called pure infall stage was sought by many astronomers. The search for unique collapse signatures in dense cores with and without stars has been carried out by way of spectroscopic observations of molecular species that trace high density (like HCO⁺, CS, and N₂H⁺). But surprisingly, the first YSOs studied with molecular spectroscopy showed evidence for expansion signatures rather than collapse signatures. In fact, it was discovered that most if not all protostellar objects have vigorous bipolar

outflows (see “► [Bipolar Flow](#)”) that are predominantly molecular and extend sometime to parsec scales from the driving source (see Snell et al. 1980 for the discovery of molecular outflows). It is now understood that outflows originate from YSOs due to angular momentum conservation issues. Observations indicate that the specific angular momentum of cloud cores is 6 orders of magnitude larger than the material on the surface of typical stars. The tendency of collapsing material to preserve specific angular momentum causes the infalling material to form a flattened structure or disk around the protostellar core (the accretion disk; see also “► [Protoplanetary Disk](#)”). At the end of the twentieth century, the Hubble Space Telescope obtained spectacular images of circumstellar disks at optical and infrared wavelengths by imaging the dusty optically thick disks in dark-silhouette against the bright reflection nebula (e.g., O’Dell and Wen 1994; Padgett et al. 1999). At millimeter wavelengths, the dust emission of the disks is usually optically thin and can be easily imaged at high-spatial resolution with interferometers, such as ALMA. Molecular line emission of CO and isotopologues at millimeter wavelengths also allows us to study the kinematics of the disks. Observations suggest that circumstellar disks can range from a few hundred to a few thousand AU in diameter. The initial mass of the protostar is only $0.01 M_{\odot}$, not enough to increase the internal temperature to the stage of nuclear ignition. The embryonic star will have to accrete more material from the disk in order to build up mass. Material in the disk can fall into the star only if it loses angular momentum. Viscous accretion can result in the net outward transport of angular momentum, thereby allowing material to fall in (Lyndon-Bell and Pringle 1974). However, we still have the problem that material at the inner edge of the accretion disk has higher angular momentum compared to the star. Nature invented bipolar outflows to get rid of this angular momentum problem.

Bipolar outflows are a manifestation of primary winds generated by the protostar itself, and are typically traced at millimeter and centimeter wavelengths by transitions of CO. Close to the surface of the star, the wind appears as highly collimated circumstellar jets. These jets are hot

and ionized and emit radiation from optical to centimeter wavelengths. Typical jet tracers at near- and mid-infrared wavelengths are ro-vibrational and rotational transitions of H_2 and forbidden lines such as [Fe II], [S I], [S II], [O I], and [Ne II], while at millimeter and centimeter wavelengths, the most typical tracer is silicon monoxide, SiO. Such jets are often seen to terminate in bow-shock structures called Herbig-Haro (HH) objects. Further away from the star, these winds sweep up massive amounts of molecular material which shows up as bipolar molecular outflows.

Bipolar outflows are highly energetic and pack mechanical luminosities that are appreciable fractions of the total radiant luminosities of these objects. Observations indicate that the mechanical luminosities of these outflows are proportional to the rate at which they are accreting matter. It is becoming increasingly clear that the sizes of these outflows can completely dwarf the putative accretion disk, reaching parsec scales in many cases. One consequence of an accretion driven outflow is that this expanding material tends to disperse the surrounding material, thereby ultimately limiting the mass accreted onto the star.

During the earliest phases of protostellar evolution, the young star is completely surrounded by the disk and envelope structure and emits like a blackbody with its peak in the far infrared. This stage is called the Class 0 phase. As the putative outflow disperses the surrounding material and the accretion disk and the embedded star are revealed, at least from the polar directions, the spectral energy distribution (SED) shifts its peak into the near infrared and subsequently into the optical part of the spectrum, with a large infrared excess compared to regular main sequence stars. These phases are called Class I, II, and III (see “► [Spectral Classification of Embedded Stars](#)”). Observationally, the early stages are best studied at submillimeter wavelengths. Gradually, as the circumstellar material is dispersed, the protostar becomes revealed in the mid- to near-infrared, which can be studied with sensitive observations with space telescopes like Hubble, Spitzer, and Herschel, and especially with James Webb in the near future.

Planet formation probably commences quite early in the evolution, with the infalling dust settling down into the midplane of a circumstellar disk due to drag forces resulting from interaction with the gas in the disk (e.g., Lissauer 1993). Micron-sized dust particles collide and merge together to form increasingly more massive and larger particles. Once they reach kilometer size, they are called planetesimals. Planets are theorized to form from the mutual accretion of planetesimals. Such planets can grow massive enough to create gaps in the circumstellar disk. Such gaps were observed for the first time at millimeter wavelengths using ► [ALMA](#) (e.g., HL Tau: ALMA Partnership 2015), and later on, in scattered light at optical and near-infrared wavelengths (e.g., TW Hydrae: van Boekel et al. 2017). High-angular resolution observations at millimeter and infrared observations have revealed that protoplanetary disks exhibit a variety of morphologies, with not only gaps, but also rings and spirals (see e.g., Andrews et al. 2018).

Future Directions

The study of star formation is going through a golden period thanks to the current and planned new instrumentation. The increasing sensitivity and angular resolution achieved at submillimeter/millimeter wavelengths with ALMA and infrared wavelengths with, for example, the VLT will allow us to study the star formation process down to the smallest scales, close to the forming stars and planets. Only then will a complete picture of the entire process from large-scale GMCs to small protoplanetary disks and forming planets will be available. In the near future, the JWST space telescope will provide the sharpest and most accurate picture of the warm dust and molecular gas in young stars and protoplanetary disks, in particular at mid-infrared wavelengths, difficult to observe from the ground.

Definition

The theory of star formation aims at understanding the physical processes, which drive the evolution of the interstellar medium from a very dilute gas into a dense medium in which nuclear reactions take place. It covers a very broad range of spatial and temporal scales that go from the giant molecular clouds, whose sizes are several tens of light years, to the stars themselves. It is believed that this evolution is largely triggered by gravity, magnetic field, turbulence, thermodynamics, as well as stellar feedback.

Overview

The interstellar medium within galaxies is filled by a gas, out of which stars eventually form. This gas presents a complex multiscale structure with temperatures ranging from 10 to 10^6 K and densities from 0.01 to at least 10^6 cm⁻³ and beyond. However, it remains much less structured than the stars themselves which occupy a tiny fraction of the galaxy volume but contain most of their (baryonic) mass. The star formation theory (Stahler and Palla 2005; Ward-Thompson and Whitworth 2011) aims to understand exactly how this transition, from a continuous to a discrete media, arises. This question bears important consequences for our universe. Not only stars are its building blocks but they strongly influence the evolution of galaxies through the feedback that the most massive stars exert during their life time, in particular at the end of their life when they explode in supernovae. Low-mass stars are also fundamental for it is well established now that they are hosting planetary systems like ours. Last but not least, stars synthesize heavy elements such as carbon and oxygen that drastically modify the thermal properties and the structure of the galactic gas and eventually permit the existence of complex molecules and life.

Historically a few outstanding questions have dominated the field of star formation although eventually many more should be addressed. The first challenge is to understand the efficiency at which stars formed in our Galaxy, a quantity also called the star formation rate (Kennicutt and Evans 2012). The second major issue is to understand the mass distribution of stars. Indeed, the properties of stars are largely determined by their masses. The mass distribution of stars is usually called the initial mass function (Offner et al. 2014; Lee et al. 2020). Finally, many stars are not isolated but are binary that is to say possess at least a companion whose distance may vary from less than an astronomical unit to a fraction of parsec. Understanding exactly how this happens as well as the characteristics of binary systems is another challenge for star formation theory. More recently with the discovery of extrasolar planets, which form within circumstellar disks, the

question of the disk formation, closely connected to the formation of binary systems, also became a major topic.

Various physical processes are triggering the evolution of the interstellar medium and eventually determine the star formation process (MacLow and Klessen 2004; McKee and Ostriker 2007). First of all, the gravitational force induces the formation of self-gravitating entities such as molecular clouds and dense cores that eventually collapse to form stars. An important concept has been inferred by Jeans (1902), the so-called Jeans length (Ward-Thompson and Whitworth 2011), which determines the spatial scale above which a cloud of a given density and temperature is prone to gravitational instability. To determine whether a cloud collapses or not, one must compare the time needed for this cloud to contract gravitationally (the freefall time) with the time needed for the sound waves to cross it. If this time is shorter than the freefall time, then the sound waves are unable to erase the density perturbations, which develop under the influence of self-gravity. Second, supersonic turbulence (Elmegreen and Scalo 2004; Scalo and Elmegreen 2004; Hennebelle and Falgarone 2012) is playing a major role in the interstellar medium, particularly in molecular clouds. On one hand, turbulent eddies tend to disperse their gas, thus contributing to reduce the efficiency of star formation. Indeed, if there was no support to resist the gravitational force, the number of stars formed each year in the Galaxy would be around 300, hundred times more than what is currently observed. However, turbulence is playing a dual role because it also compresses the gas locally through shocks. The spectrum of density fluctuations, which is then generated, may have fundamental consequences by setting the mass of the stars and being at the origin of their mass spectrum. Magnetic field is another physical process that likely has important consequences. Indeed, it has even been believed that magnetic field could be strong enough to be entirely responsible for the low star formation rate measured in the Milky Way (Shu et al. 1987). The idea was that because the ionization of the molecular clouds is rather low, most of the gas is not subject to the magnetic Lorentz force; thus, ionized species

could drift away carrying with them the magnetic field lines and reducing the magnetic intensity to the point where magnetic field would not be dominant anymore. Although this remains a controversial issue, the recent observational measurements seem to indicate that magnetic fields, while not negligible, are not dominant. Magnetic field however is having nevertheless a significant impact on the star formation process because it may contribute to reduce somehow the star formation efficiency. It also modifies the statistical properties of the supersonic turbulence, and finally during the collapse, it contributes to reduce the rotational support by transporting the angular momentum of the gas from the inner to the outer part of the collapsing cloud. As the collapse proceeds, the centrifugal force becomes more and more important and stops the gravitational infall, thereby leading to the formation of centrifugally supported disks. This process known as the centrifugal barrier requires the existence of various mechanisms to transport the angular momentum (Bodenheimer 1995; Hennebelle et al. 2013) and to permit the accretion onto the protostars. Angular momentum is at the origin of binary stars and planets. Indeed, the formation of a few objects orbiting around their center of mass constitutes an efficient way to store the angular momentum of the cloud. In the solar system, for example, the angular momentum of Jupiter is by far the dominant contribution. It is comparable to the angular momentum, which is believed to be typical for the prestellar core that led to the formation of the sun.

Finally, it is now well established that the feedback induced by the massive stars during their life, such as powerful winds, ionizing radiation, or protostellar jets, and particularly as they die and explode in a powerful supernovae, plays a major role in star formation (MacLow and Klessen 2004). First of all, this feedback is most probably an important source for the galactic turbulence. Second, the stellar feedback likely disperses the cloud in which the massive stars have formed and therefore significantly limits the star formation efficiency which otherwise would be far larger than the value deduced from observations.

Basic Methodology

Star formation appears to be a complex multi-scales and multiphysics problem. As such, it is necessary to combine various approaches to make progress in this field. First of all, high-resolution observations must be carried out using the most accurate telescopes at various wavelengths. Second, due to the complexity of the equations, which govern the fluid evolution, star formation theory makes extensive use of the numerical simulations. These calculations are performed on massively parallel supercomputers. They require millions of computer hours and generate terabytes of data. To solve the fluid equations accurately, complex algorithms have been developed such as Riemann and Poisson solvers (Teyssier 2002; Springel 2005). In parallel, one also needs to develop simpler analytical calculations for some of the key processes and to confront the results and the predictions with the numerical simulations. Such approach is necessary to assess the simulation results but also to identify and understand the nonlinear phenomena at play.

The numerical models take into account the microphysical properties of the chemical elements contained in the interstellar medium and determine, for example, the rate at which it cools or forms complex molecules (Le Petit et al. 2006). The knowledge of these microphysical processes is also a challenge, which requires dedicated observations, laboratory experiments, and heavy calculations. Third, the comparison between observations and theory is another necessary and complex step. To achieve this goal, it is sometimes necessary to produce synthetic observations using the models. That is to say, one needs to simulate the luminous signal, which would be observed if an object like the model was observed with a telescope (Commerçon et al. 2012).

Keywords

Star formation · Young stellar object (YSO) · HII region

Definition

► **Star formation** takes place in ► **molecular clouds** and occurs via two ways that can be either spontaneous or triggered. In the triggering case, an external agent (compression) acts as a precursor. This extra pressure has different origins and favors the collapse of molecular condensations to form stars. One mechanism of triggered star formation is based on the expansion of HII region around massive stars, but massive stars also impact on their surrounding via winds and supernova explosion at the end of their life. Recent multi-wavelength and multiscale data sets in our galaxy have shed light on star formation processes and revealed how important feedback processes may be.

Overview

Massive stars ($M > 8 M_{\odot}$) are rare and evolved rapidly, but they play a crucial role in the chemical

and dynamical evolution of galaxies. They produce a high amount of ultraviolet photons that can ionize the surrounding medium, especially neutral hydrogen (HI). This leads to the creation of an ionized (HII) region that expands in the surrounding medium, due to the temperature difference between the hot inside region and the cold surrounding gas (Dyson and Williams 1997). Massive stars also impact on their surrounding via winds and supernova explosion at the end of their life. They create heavy elements that are expelled and enrich the surrounding interstellar medium. Blaauw and Morgan (1953) first observed a sort of “in chain reaction” in the formation of massive stars, suggesting that the massive star HD34078 was formed in a compression region of a nebula that might have been itself pushed away from the Orion region. In a subsequent review, Blaauw (1964) observed spatial separation of OB subgroups with different ages. This observation leads Elmegreen and Lada (1977) to propose a mechanism of triggered star formation based on the expansion of HII regions. This mechanism has been called the collect and collapse model as a layer of material is collected during the expansion of the ionized region and then collapses to form fragments where new stars may form. With the progress made in infrared detectors and all-sky infrared surveys, it becomes clear that an over-density of young stellar objects is observed at the edges of HII regions in our galaxy and in external galaxies. In 2005, Deharveng et al. published a paper where, using the results from the Spitzer telescope, they studied in the infrared a series of Galactic HII regions where triggered star formation was likely to occur. Starting from this study, many international groups have worked on this subject with the aims to characterize the physical mechanisms responsible for this way of forming stars and to quantify its importance.

Multi-wavelength large-scale surveys together with pointed observations reveal active ongoing star formation at the edges of galactic and extragalactic HII regions (Deharveng et al. 2005; Zavagno et al. 2007; Galametz et al. 2013; Bernard et al. 2016). In the study of triggered star formation by expanding HII regions, the key question is to

establish the causal link, if any, between a given HII region's expansion and the star formation observed at its edges. One also wants to understand the physical mechanisms that control this way of forming stars (Schneider et al. 2020) and to quantify the importance of this phenomenon on a galactic scale (Palmeirim et al. 2017).

Massive stars form ionized regions. These regions expand in the surrounding medium at a supersonic speed ($v \sim 10$ km/s) creating a shock front preceding the ionized front. During the expansion of the HII region, neutral material accumulates between the ionization front and the shock front. A layer of dense neutral material builds up around the ionized region. With time, this layer becomes massive and a new generation of stars may form in it. This phenomenon is called triggered star formation by the expansion of ionized regions (Fig. 1).

Basic Methodology

In the study of star formation triggered by the expansion of HII regions, the first step is to detect

and to characterize the properties of YSOs that are observed at the edges of HII regions. Images give two-dimensional information, and the observed young stellar objects (which are stars in the process of forming) may not be associated with the observed HII region we are looking at but may be a by-chance projection observed on the line of sight. Complementary spectroscopic data give information on the velocity of the YSOs and the ionized region and allow to demonstrate the real association of the YSO with the ionized region. The physical properties of the YSOs (luminosity, mass, age, evolution stage) can be obtained by measuring their flux at different wavelengths covering a large spectral range (ideally from the optical to the millimeter) and by fitting the complete set of fluxes with theoretical models that predict their evolution. The early stages of star formation are also characterized by a strong dynamical and chemical evolution. Such information is obtained with spectroscopic data and is also crucial in our determination of young stellar objects' age. Indeed, the triggered star formation mechanism supposes that the first generation of massive star (s) that creates the ionized region has to be older than the YSOs observed at its edges, if a causal link exists between the expansion of the ionized zone and the further formation of YSOs observed on its edges.

Key Research Findings

Many recent infrared and submillimeter surveys have shown that we are living in a "bubbling galactic disk" where thousands of ionized regions are observed with bright YSOs sitting at their edges (Deharveng et al. 2010; Kendrew et al. 2012). These authors have shown that triggered star formation seems to be an efficient way of forming massive stars as at least 30% of the massive YSOs are observed at the edges of HII regions in the galaxy (Palmeirim et al. 2017, Kumar et al. 2020). Deharveng et al. (2010) have shown that many physical mechanisms can be responsible for triggered star formation at the edges of HII regions. Among these are small-scale gravitational instabilities, large-scale gravitational instabilities that lead

Star Formation, Triggering, Fig. 1 RCW 120: a galactic HII region with active star formation observed with the infrared Herschel satellite and the PACS and SPIRE instruments (Credits: ESA/PACS & SPIRE Consortium, Dr. Annie Zavagno, LAM, HOBYS Key Programme Consortia)

to the formation of high-mass fragments, ionizing radiation acting on a turbulent medium, and radiation-driven compression of preexisting dense clumps. All these mechanisms can act at the edges of a given ionized region.

Herschel observations of Galactic HII regions compared with results of numerical simulations show that the expansion of the ionized region has a real impact in increasing the density at the edges of the ionized gas and that compression from the ionized gas really impacts on star formation (Minier et al. 2013; Tremblin et al. 2015). Radiative compression occurs at the edges of HII regions and enhances the local density (Zavagno et al. 2020). However, numerical studies (Dale et al. 2013) show that it is very difficult to separate the preexisting and triggered star formation at the edge of ionized regions. Herschel data provide a lot of key information especially on the structure of the dense regions that surround HII regions that allow us to really characterize the role of these regions in the star formation observed at their edges. Billot et al. (2011) used a minimum spanning tree algorithm to characterize the spatial distribution of galactic far-IR sources and derive their clustering properties using the results of the Herschel infrared GALactic (Hi-GAL) plane survey (Molinari et al. 2010). They show that protostars surrounded by warm molecular material and detected at short infrared wavelengths tend to be clustered in dense and compact groups around HII regions. Detailed studies of galactic ionized regions such as Gum 31 (Ohlendorf et al. 2013) show that the location of associated YSOs in the photodissociation region is suggestive of their being triggered by a collect and collapse scenario. However, the study of an infrared dark filament in interaction with an HII region (Tackenberg et al. 2013) shows that the evidence for triggered star formation there is not obvious, even if a massive (preexisting) clump is observed. The difficult point remains to prove that the collapse that will lead to star formation is really favored by the expansion of the ionized region.

Recent statistical studies and multiscale analysis (from >10 pc to the core scale <0.01 pc) of a sample of high-mass starless clumps (HMSCs) that are expected to represent the earliest (and

still unperturbed) stages of high-mass star formation bring very interesting results: Zhang et al. (2020, 2021) show that the HMSCs associated with HII regions have different physical properties (luminosity and temperature) than the ones observed away from HII regions. The HMSCs associated with HII regions (i.e., observed at their edges) are also more turbulent. This demonstrates for the first time the physical impact from HII regions on massive clumps at the very early stages of their formation.

Future Directions

The wealth of data provided by the Herschel satellite, combined with high-resolution ALMA data and forthcoming data such as the ones provided by the JWST, allow an in-depth study of the star formation in our galaxy and in external galaxies.

The global view we have with large imaging and spectral surveys allows to study the triggered star formation phenomenon and to quantify its importance on galactic scales. This global view will be complemented with detailed, high-resolution pointed observations in the infrared with ground- and space-based facilities and in the millimeter with the ALMA interferometer. The idea with high-resolution pointed observations is to go in depth in our understanding of the physical mechanisms that control star formation on small spatial scales, including fragmentation of clumps into cores on spatial scale <0.01 pc, whatever the way (either spontaneous or triggered) of forming star is. Future observing facilities either ground and space based go in this direction of high resolution. The James Webb Space Telescope (JWST) and the Extremely Large Telescope (ELT) will play a crucial role in this context. All the knowledge that will be gained with these observations will help to further constrain the theoretical models that describe with more and more details the mechanisms that control star formation. The possibility to address this issue in external galaxies will also become possible with these high-resolution and high-sensitivity facilities.

Recently, the role of magnetic field in the star formation process has gained much interest in

research, mainly driven by the progress in magnetic field measurements (Bracco et al. 2020). The study of the magnetic field observed toward HII regions and its role in star formation will be a major research topic in the coming years.

Some of the key questions that still have to be addressed are:

- How important and how efficient is this way of forming stars? Herschel images revealed highly embedded sources that were not detected before at the edges of HII regions. This means that these sources were not “counted” and that their presence, if firmly related to the impact of the ionized region, will increase the efficiency of this way of forming stars. Spectroscopic studies show that most of the young sources observed at the edges of HII regions are physically associated with them (Martins et al. 2010). However, in some cases, the sources are not associated with the ionized region, contrary to what is suggested by two-dimensional images. This result also changes the statistics, as soon as a non-associated young source may be counted (as being under the influence of the ionized region) if no spectroscopic information exist for it. The existence of spectroscopic data will improve this situation, allowing a clear association between YSOs and HII regions.

The high-resolution ALMA data offer a unique opportunity to address this question by looking at the central part of the clumps located at the edges of HII regions. The fragmentation of these clumps form the cores that will form the future stars. Looking at the population of cores in clumps allows to study this process at the heart of star formation, especially for clumps observed at the edges of HII regions compared to clumps observed away from HII regions (Zhang et al. 2021).

- What are the mechanisms that control star formation at the edges of HII regions? Observations and comparison with numerical simulations are needed now to understand the different physical processes that take place to possibly favor star formation, including a careful treatment of the radiative transfer of the

incoming radiation from the ionized region onto the dense clump that will host the future star formation. The role of turbulence and magnetic field at small and large scale in the star formation process in general and in this specific way of forming stars in particular is still not clear. Zhang et al. (2020) show that the physical properties of massive clumps are changed at the edges of HII regions when compared to similar clumps observed away from HII regions. The physics of this change has to be modeled and understood, including all the physical ingredients.

- What is the impact of HII region in the mass distribution of young stars that form at their edges? The study of the initial mass function (IMF) is a key question in astrophysics. A systematic study of young clusters at high resolution has to be done to address this question. The combination of high-resolution and high-sensitivity data in the infrared with the JWST and with ALMA in the submillimeter range is very promising for this topic.
- What is the importance of this phenomenon in external galaxies? High resolution allows to study this phenomenon in external galaxies and to see how it proceeds under specific environment, including low-metallicity galaxies. If massive stars can trigger the formation of a new generation of massive stars, this phenomenon may be important for cosmology and the formation of the first massive stars in the universe. On this topic also, the combination of ALMA and JWST data offers a very bright future.

Definition

Stardust is a spacecraft mission which returned to Earth samples from the ► [comet Wild 2](#). The main objective of the mission was to contribute to the understanding of the evolution of the solid matter which marked the passage of the interstellar matter in the solar nebula and constrain models of formation and evolution of dust particles in the protoplanetary disk.

Overview

Stardust is a ► [NASA](#) mission whose main objective was to collect samples in the coma of the

comet Wild 2. The spacecraft was launched on February 1999 and returned to Earth on January 2006. It is the first sample return mission to collect cometary dust. These cometary particles are believed to be relicts of the primitive material of the early solar system. Their sojourn in a comet nucleus probably allowed the preservation of primordial signatures. The main scientific objective of the mission was to understand the evolution of solid matter which marked the passage of the interstellar matter in the solar nebula and constrain models of formation and evolution of dust particles in the protoplanetary disk.

The cometary dust in the coma was trapped at a relative velocity of 6.1 km/s using a dust collector which contains ultralow-density aerogel trays. The role of the aerogel was to reduce the particle speed gradually in order by the temperature rise to minimize the physical and chemical alteration due to the high-velocity capture. A large number of particles were returned to Earth and were studied using various investigation techniques by several international laboratory consortia.

The impact of particles in aerogel generated deceleration tracks in which the cometary material is unevenly distributed in various proportions. The largest particles were found well preserved from the hypervelocity impact. Their study showed that most of them display clear evidence for high-temperature processes that likely occurred at the inner edge of the ► [protoplanetary disk](#) before the accretion on the comet. On the opposite, the fine-grained material shows clear evidences of thermal modification in addition to strong intermixing with the aerogel due to the capture process at very high velocity. This thermally modified material originates from fine-grained, loosely bound, dust aggregates for which the composition is close to the solar photosphere or the most primitive ► [meteorites](#).

Particles returned by the Stardust spacecraft show that the comet Wild 2 accreted “cold” dust from the icy parts of the outer solar system and also thermally processed particles coming from the inner region close to the Sun. The protoplanetary disk at the accretion stage of the ► [solar nebula](#) period was thus animated by large radial mixing.

Keywords

Stars · Hydrostatic equilibrium · Radiative equilibrium · Molecular cloud · Nuclear reactions · Nucleosynthesis · Chemical enrichment

Definition

Stars are spheres of plasma in hydrostatic equilibrium, where the inward force of gravity is balanced by the outward gas pressure. The energy source for the gas is gravitation, sustained and prolonged by nuclear energy resulting from

thermonuclear fusion reactions in the hot stellar interior. Stars form by contraction of a portion of a molecular cloud.

Overview

Stars are spheres of gas that can most of the time be considered as in hydrostatic and radiative equilibrium. They form during the contraction of cold molecular clouds. In the process of star formation, a part of the original matter of the cloud may form a disk around the star, and in such a disk, planets could be built.

At the center of the collapsing cloud, the temperature rises until it is sufficient for nuclear reactions to take place; thus, a new star is born. Through these reactions, new chemical elements are synthesized (→ nucleosynthesis) accompanied by a production of energy. The energy release sustains the star against its own gravity. Successive fusion phases can be identified in the course of the evolution of stars: deuterium and lithium at the very beginning of the evolution and then hydrogen (→ main sequence). Stars more massive than 0.5 Msol go on with a phase of helium fusion (“burning”), and the ones more massive than 8–9 Msol enter the advanced phases: carbon burning, neon photodisintegration, oxygen, and eventually silicon burning.

The way stars end their evolution depends on their initial mass: below 8 Msol, they experience a strong wind evaporating their external layers, and they end as white dwarfs surrounded sometimes by a planetary nebula. Between 8 and 10 Msol, they ignite carbon in degenerate conditions, building an O-Ne core. If the core at the end of C burning is large enough, the star can explode in what is called an electron-capture supernova (→ supernova); otherwise, it ends its life as an O-Ne white dwarf. Above 10 Msol, stars end their evolution in the explosion of a supernova. The remnant may be a neutron star or a black hole, depending on the mass of the iron core at the time of the collapse.

Stars are the source of most heavy elements in the Universe (there is also the phenomenon of spallation by cosmic rays). The products of nucleosynthesis that occurs in their core are spread in

the interstellar medium by the winds or the supernova explosion, contributing to the general chemical enrichment of the Universe.

Šteins

Ekkehard Kührt
Institute of Optical Sensor Systems, German
Aerospace Center, Berlin, Germany

Definition

Asteroid 2867 Šteins is a main-belt asteroid of the rare spectral E-type with an effective spherical diameter of 5.4 km and a rotation period of about 6.05 h. The interior structure is thought to be a rubble pile. On September 5, 2008, the Rosetta Spacecraft flew by Šteins at a distance of 800 km with a speed of 8.6 km/s and collected a great amount of scientific data.

History

Asteroid 2867 Šteins was discovered in 1969 by the Soviet and Russian astronomer, Nikolai S. Chernykh. It is named after Kārlis Šteins, a Soviet and Latvian astronomer.

Stellar Cluster

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Definition

Stars located in the same region that move together through space must be physically related and indeed must share a common origin – such stars form a stellar cluster. Within our own galactic neighborhood, all stellar clusters are relatively young and eventually disperse. In some groups, called open clusters, the coherence is maintained by the mutual gravitational attraction of the member stars. In others, called T associations, the stars are gravitationally bound to a parent ▶ [molecular cloud](#). OB associations, a third type, are unbound and actively dispersing. The very youngest stars are in groups so deeply embedded in cloud gas that they can be detected only in the infrared or submillimeter wavelength ranges.

Keywords

Stars · Stellar physics · Internal stellar structure

Definition

Stellar evolution refers to the changes in the internal and global properties of stars during their lifetime.

Overview

Stars are fundamental entities providing light and energy in the Universe, as well as producing most of the chemical elements. The study of their internal structure and evolution is thus at the basis of astrophysics. In addition, since many stars host planetary systems, their study is a basic aspect of astrobiology. In this entry, the basic concepts of stellar evolution are first introduced by deriving the equations describing the evolution of the internal structure of a star. These equations are then used to obtain simple analytical estimates of stellar properties and to qualitatively understand the different phases of stellar evolution in terms of basic physical considerations. The evolutionary scenarios obtained by numerically solving the equations of stellar evolution are then discussed for stars with different initial masses. In addition to this global view of standard stellar evolution, the inclusion of nonstandard-stellar physics is finally briefly discussed together with the future developments expected in the field. Since this entry only provides a brief overview of stellar evolution, readers interested in a more in-depth description of the subject are referred to the books already available in the literature (e.g., Kippenhahn and Weigert 1990; Prialnik 2000; Hansen et al. 2004; de Boer and Seggewiss 2008; Maeder 2009).

Basic Methodology

Hydrostatic Equilibrium

To understand stellar evolution, we first note that most stars are in such long-lasting evolutionary phases that no significant changes in their global properties can be directly observed. Indeed, during the main part of their life, stars are in mechanical equilibrium or hydrostatic equilibrium. This

implies that all forces acting on a given element of the star compensate each other. To prevent the gravitational force from accelerating a mass element toward the center, a force of the same absolute magnitude must be acting outward. This force is due to pressure and, more precisely, to the pressure gradient present in stellar interiors. The equation expressing the hydrostatic equilibrium of a star can be very simple derived by considering a thin shell in a spherically symmetric star with a radius r and $r + dr$ with pressures of P and $P + dP$, respectively. The radius r is defined here as the distance to the stellar center. The difference of pressure dP between r and $r + dr$ is then balanced by gravitation such that

$$dP = -\rho g dr, \quad (1)$$

with ρ is the density and g the magnitude of the vector gravity directed toward the stellar center. By defining M_r as the total mass interior to the radius r , Newton's Law of Gravitation gives $g = GM_r/r^2$ where G is the constant of gravitation, and then,

$$\frac{dP}{dr} = -\frac{GM_r}{r^2} \rho. \quad (2)$$

This equation of hydrostatic equilibrium constitutes the first basic equation describing the structure of a star. It simply means that at any point in the interior of a star at equilibrium, the pressure gradient sustains the stellar matter against the gravity force.

The second basic equation governing the structure of a star concerns the variation in mass within a star and is directly related to the conservation of mass. In spherical symmetry, the change of the mass M_r contained in a sphere of radius r is given by

$$dM_r(r, t) = 4\pi r^2 \rho dr - 4\pi r^2 \rho v dt. \quad (3)$$

The first term on the right-hand side of this equation corresponds to the change of mass resulting from a variation in the radius r at a given time t , while the second term represents the flux of mass out of the sphere of radius r due

to a motion with velocity v . At equilibrium, this velocity v equals 0, and we are left with the following equation:

$$\frac{dM_r}{dr} = 4\pi r^2 \rho. \quad (4)$$

This is the second basic equation describing the internal structure of a star. It is interesting to note that if the pressure P is a function of the density ρ alone, Eq. 4 together with Eq. 2 form a complete set of equations describing the structure of the star. However, under normal stellar conditions, pressure also depends on temperature. This means that the presence of a pressure gradient required to achieve hydrostatic equilibrium also results in a gradient in temperature inside the star. The central layers of a star are then found to be hotter than the superficial layers. Recalling that a higher temperature leads to a larger amount of energy contained per unit volume in the radiation field, an energy flow will take place from the central parts to the stellar surface, so that a star continuously loses energy. The luminosity (total energy radiated per unit time) of the star is then a direct consequence of hydrostatic equilibrium: stars evolve because they lose energy in order to counteract the gravitational force and to achieve hydrostatic equilibrium. The sources of this stellar energy will directly influence the evolution of the star and the duration of the various evolutionary phases.

Energy Production

Gravitational contraction is a major source of stellar energy. By a global contraction, a star can indeed directly extract energy from the gravitational potential. Conversely, an expansion of the star leads to an absorption of energy and a decrease of its luminosity. This production of energy takes place on a characteristic timescale called the Kelvin-Helmholtz timescale τ_{KH} . This timescale can be simply calculated from elementary physics, such that the global gravitational energy Ω of a star of mass M and radius R is given by $\Omega = -qGM^2/R$ (with $q = 3/5$ for a constant density). The star will then be able to produce an average luminosity L at the expense

of its gravitational energy on a timescale given by this energy divided by the energy production per second:

$$\tau_{KH} = \frac{\Omega}{L} \approx \frac{GM^2}{RL}. \quad (5)$$

For the Sun, this gives a typical value of about 3×10^7 years. This lifetime of a few tens of million years is, of course, too short to be in agreement with our knowledge of the past history of the Earth. This indicates that another main source of stellar energy exists.

In addition to gravitational contraction, a star can produce energy by thermonuclear reactions in its central layers where the physical conditions in terms of temperature and density needed for such processes to occur are met. The timescale of energy production through nuclear reactions can be simply estimated from the hydrogen-burning phase, the longest phase of stellar evolution, during which the fusion of hydrogen into helium occurs (astronomers refer to nuclear fusion as “burning”). The hydrogen burning transforms four protons into one helium nucleus with a release of energy due to a relative mass defect of about 0.007. Simply speaking, this means that 1000 g of hydrogen is converted into 993 g of helium, while 7 g is transformed into energy, where $E = mc^2$. The characteristic timescale associated with this reaction can then be expressed as the ratio of the total energy that can be created by this process to the stellar luminosity, the analogue of Eq. 5. If nuclear reactions would take place in the whole star of total mass M , this energy would be equal to $\Delta Mc^2 = 0.007 M$ (with c the speed of light). However, nuclear reactions only take place in the central parts of the star, so that this energy estimate has to be corrected by a factor q equal to the fraction of the stellar mass where nuclear reactions occur. This leads to the following timescale of energy production by nuclear reactions:

$$\tau_H \approx 0.007 \frac{q_c Mc^2}{L}. \quad (6)$$

For the Sun, this estimate gives a typical lifetime of 10 billion years (with $q_c = 0.1$), which is in

agreement with our knowledge concerning the past history of the Earth. These very simple estimates of characteristic timescales for the stellar energy production show that nuclear reactions are of major importance to understanding how a star can shine during long durations. Nuclear energy is, however, not absolutely necessary to explain the observed stellar luminosities, since a star can be shining even without nuclear reactions in its core (but only on limited timescales) thanks to the energy production by gravitational contraction. The role of nuclear reactions is of course not limited to the energy equilibrium of the star, since nuclear reactions transform chemical elements in stellar interiors and are therefore at the basis of stellar nucleosynthesis.

The energy conservation in a star leads to the third basic equation for stellar structure. It simply implies that the gain of energy in a mass element is equal to the difference between the energy produced and the energy escaping. With the hypothesis of spherical symmetry of the star, it can be shown that the equation of energy conservation can be written as

$$\frac{\partial L_r}{\partial r} = 4\pi r^2 \rho (\varepsilon + \varepsilon_{\text{grav}}), \quad (7)$$

where L_r is the luminosity at radius r , ε is the energy produced by nuclear processes per unit of time and mass, and $\varepsilon_{\text{grav}}$ is the energy provided to the system due to a change of structure.

Energy Transfer

Like the mechanical equilibrium of the star, its energetic equilibrium plays a key role in determining its structure and evolution. This equilibrium describes the balance between the energy production discussed in the preceding section and its transport to the stellar surface. The energy production rate of a star regulates itself to reproduce the radiative losses at the surface. In this sense, a star can be considered as a self-controlled nuclear reactor. Assuming that more energy is produced in the stellar center than what can be transported to the surface would lead to an accumulation of energy in the central layers resulting in an expansion of the star. The internal pressure

and temperature would then decrease as a result of this expansion, thereby reducing the energy production rate by nuclear reactions. The transport of energy in the interior of a star is thus of prime importance to determine its structure. The transport by photons, or radiative transfer, plays the main role. Convection is another important process for the transport of energy, but it generally occurs only over limited zones of the stellar interior, while radiative transfer is present in the whole interior. Conduction by electrons is the third process for the transport of energy; it only plays an important role in degenerate conditions (e.g., in white dwarfs).

To discuss radiative transfer in stellar interiors, we first consider a photon emitted in the central layers of a star. This photon will be rapidly absorbed by an atom, then re-emitted in a random direction, reabsorbed by another atom, re-emitted, and so on until it reaches the stellar surface. The length of the mean path of this photon between two interactions, which is called the mean free path, is much smaller than the stellar radius. In the case of the Sun, this mean free path is indeed approximately equal to 0.01 cm in the center and 1 cm in the envelope (near the surface, this value may of course be much larger given the very low density of the external layers). Thus, sometime will be spent before a photon emitted in the stellar core reaches the surface; in the case of the Sun, this value is typically of the order of ten million years.

In addition to the photon mean free path, another quantity is important in the context of radiative transfer: the mean gradient of temperature inside the star. This value can be roughly estimated by using the solar values of radius and central temperature:

$$\begin{aligned} \left\langle \left| \frac{dT}{dr} \right| \right\rangle &\approx \frac{T_{\text{central}} - T_{\text{surface}}}{R} \approx \frac{T_{\text{central}}^{\text{sun}}}{R_{\text{sun}}} \\ &\approx 10^{-4} \text{ K cm}^{-1}. \end{aligned} \quad (8)$$

Comparing this value with the photon mean free path and recalling that temperatures in the internal layers of the Sun are typically of the order of ten million K, we see that the relative

variation of the temperature is very small over the mean free path of a photon. This implies that the radiation field in a star can be well described by the radiation of a blackbody with the local value of temperature T : this is called local thermodynamic equilibrium (LTE). From this, we can ultimately derive the fundamental equation of radiative transfer:

$$F = \frac{L_r}{4\pi r^2} = -\frac{4acT^3}{3\kappa\rho} \frac{dT}{dr}. \quad (9)$$

where κ is the opacity or absorption coefficient of the stellar matter and the radiation constant a is equal to $4\sigma/c$, with σ = Stefan's constant. The radiative flux F is thus proportional to the thermal gradient.

In addition to radiation, convection can also transport energy in stellar interiors. These convective motions take place in stellar regions where a heat excess is present that cannot be transferred by radiation alone. Since the treatment of convection is a difficult task involving the complexity of turbulent motions, we only give here the basic transfer equation describing adiabatic convection, which applies in the deep stellar layers:

$$\frac{dT}{dr} = \nabla_{\text{ad}} \frac{T}{P} \frac{dP}{dr} \text{ with } \nabla_{\text{ad}} = \frac{P\delta}{C_P\rho T}, \quad (10)$$

where C_P is the specific heat and $\delta = -\left(\frac{\partial \ln \rho}{\partial \ln T}\right)_P$.

Key Research Findings

Basic Equations of Stellar Evolution

In the preceding section, the fundamental concepts of stellar evolution have been introduced to obtain the four equations that describe the evolution of the structure of a star (when rotational and magnetic effects are ignored):

- Hydrostatic equilibrium:

$$\frac{dP}{dr} = -\frac{GM_r}{r^2} \rho \quad (11)$$

- Mass conservation (continuity equation):

$$\frac{dM_r}{dr} = 4\pi r^2 \rho \quad (12)$$

- Energy conservation:

$$\frac{\partial L_r}{\partial r} = 4\pi r^2 \rho (\varepsilon + \bar{v}_{\text{grav}}) \quad (13)$$

- Transport equation:

$$\frac{dT}{dr} = -\frac{3\kappa\rho}{4acT^3} \frac{L_r}{4\pi r^2} \text{ in radiative zones} \quad (14)$$

$$\frac{dT}{dr} = \nabla_{\text{ad}} \frac{T}{P} \frac{dP}{dr} \text{ in convective zones} \quad (15)$$

The properties of the stellar matter appear through the following physical ingredients, which are required to solve these equations:

- The nuclear reaction rates are needed to evaluate the corresponding production of energy.
- The equation of state expresses the relation between the three physical parameters P , T , and ρ . For a given chemical composition, the equation of state is required to determine the third physical parameter from the two others and to obtain the thermodynamic quantities needed for the computation of a stellar model.
- The opacities are required to calculate the energy transport by radiative transfer and to determine the radiative gradient. A prescription for the energy transport by convection is also required to calculate the temperature gradient in a convective zone. In particular, the hypothesis of adiabaticity is correctly justified in deep stellar layers, but becomes inadequate for outer convective zones. In this case, an appropriate approximation has to be used, as, for instance, the standard mixing-length theory (Böhm-Vitense 1958).

Finally, together with this system of equations, the equations of the evolution of chemical element abundances are solved.

Simple Estimates of Stellar Properties and the Mass-Luminosity Relation

The general equations governing stellar evolution are, of course, too complicated to be solved analytically. The structure and evolution of a star is thus computed by numerically solving this system of equations. It is, however, interesting to notice that very simple estimates of some basic stellar properties can be directly deduced from these equations. For instance, using the equation of hydrostatic equilibrium, one can readily obtain an order-of-magnitude estimate of the pressure and temperature inside a star. First, the pressure gradient of Eq. 11 is approximated by

$$\left| \frac{dP}{dr} \right| \approx \frac{P_{\text{center}} - P_{\text{surface}}}{R} \approx \frac{P_{\text{center}}}{R}. \quad (16)$$

By also taking simple average values for the other quantities appearing in Eq. 11, $M_r < M/2$, $r < R/2$, and $\rho < 3 M/(4\pi R^3)$, one obtains an estimation of the pressure in the central parts of a star:

$$P_{\text{center}} \approx \frac{3}{2\pi} \frac{GM^2}{R^4}. \quad (17)$$

The corresponding rough estimate of the central stellar temperature can then be obtained by assuming a chemically homogeneous star with the perfect gas law:

$$P = nkT = \frac{\rho}{\mu m_u} kT, \quad (18)$$

with k the Boltzmann constant, m_u the atomic mass unit, μ the mean molecular weight (i.e., the average number of atomic mass units per particle), n the number of particles per unit volume, and ρ the density. Combining this relation with the above estimate of the central pressure (Eq. 17), we obtain

$$T_{\text{center}} \approx \frac{\mu m_u}{k} \frac{GM}{R}. \quad (19)$$

In the case of the Sun, these crude estimates give values of about $5.5 \times 10^{15} \text{ g}^{-2} \text{ cm}^{-1}$ and

$3 \times 10^7 \text{ K}$ (assuming a mean molecular weight of $\mu = 0.5$ corresponding to ionized hydrogen) for the central pressure and temperature, respectively. This shows that very high values of pressure and temperature are encountered in the deep stellar interior. These simple estimates are also significant in that they illustrate the functional dependence of these internal stellar properties on the global stellar parameters M and R .

While simple estimates of internal stellar properties can be derived from the relation of thermodynamic equilibrium, an estimate of the fundamental relation between stellar luminosities and masses can be obtained from the equation of radiative transfer. Starting from Eq. 14 with a simple approximation of the radiative pressure gradient expressed in terms of temperature

$$\begin{aligned} \frac{dP_{\text{rad}}}{dr} &= \frac{d}{dr} \left(\frac{1}{3} a T^4 \right) = \frac{1}{3} a \frac{dT^4}{dr} \\ &\approx \frac{1}{3} a \frac{T_{\text{surface}}^4 - T_{\text{center}}^4}{R} \\ &\approx -\frac{1}{3} a \frac{T_{\text{center}}^4}{R}, \end{aligned} \quad (20)$$

and with approximations for the quantities $L_r \sim L$ (with L the total luminosity) and $r \sim R/2$, one obtains

$$L \approx \frac{\pi ac}{3} R \frac{T_{\text{center}}^4}{\kappa \rho}. \quad (21)$$

Using the estimate for the central temperature derived above (Eq. 19) and the mean value of the stellar density of $\rho < 3 M/(4\pi R^3)$, this finally leads to

$$L \approx \frac{4\pi^2 ac}{9} \left(\frac{Gm_u}{k} \right)^4 \frac{\mu^4 M^3}{\kappa}. \quad (22)$$

This fundamental relation between L and M is called the mass-luminosity relation. Eq. 22 is, of course, only a crude estimation of the relation. However, it enables us to clearly illustrate some fundamental stellar properties. First, the luminosity is found to rapidly increase with the stellar mass. This increase, which is proportional to the

third power of the mass, correctly reproduces the properties of stars during the long-lasting main sequence phase of core hydrogen burning. Second, the luminosity is found to depend on the opacity κ but not on the nuclear energy production. This nicely illustrates the fact briefly discussed above that nuclear reactions enable the star to shine during long periods of time but that its luminosity depends on the ability of photons to travel through the stellar matter to reach the stellar surface.

Evolution in Degenerate and Nondegenerate Conditions

After briefly studying how basic stellar properties can be simply derived from the general equations of stellar structure, we are now interested in investigating how these properties evolve during a stellar lifetime. As discussed above in the section devoted to stellar energy production, two main sources of energy are available for a star: thermonuclear reactions and gravitational contraction. Consequently, the evolution of a star can be schematically represented as a succession of phases during which the energy is mainly produced by nuclear reactions and phases during which the energy production related to gravitational contraction dominates. Indeed, as soon as all the nuclear fuel present in the core of a star has been burnt by nuclear reactions, energy is mainly produced by gravitational contraction until the physical conditions in the stellar center enable it to ignite a new series of nuclear reactions. Thus, the temperature and density increase in the central parts of a star during its evolution as a result of the succeeding contractions. This can lead to significant changes in the physical properties of stellar matter with a transition from nondegenerate to degenerate conditions.

We recall here that degeneracy pressure is of nonthermal origin and results from quantum-mechanical effects. According to Pauli's exclusion principle, each quantum cell of the six-dimensional phase space $\{x, y, z, p_x, p_y, p_z\}$ cannot contain more than two electrons (x, y, z correspond to the space coordinates of the electrons with volume $dV = dx dy dz$, while p_x, p_y, p_z correspond to the momentum space). The

volume of such a quantum shell is defined by $dx dy dz dV$ and is equal to h^3 , with h the Planck constant. When the density increases, the volume dV is reduced so that some electrons will exhibit large impulses. These electrons with large velocities will then exert a new sort of pressure that solely depends on density and not on temperature. Note that this holds not only for electrons but also for other fermions like the neutrons.

Interestingly, the two main sources of energy production, nuclear reactions and gravitational contraction, lead to completely different effects when the stellar matter is degenerate compared to the nondegenerate case. Indeed, in nondegenerate conditions, a contraction leads to an increase of the central temperature of the star, while in degenerate conditions, a contraction may produce a cooling of the stellar matter. To illustrate these different behaviors, we first consider a uniform contraction of a given mass M . This results in a variation δr of the radius together with variations in pressure δP and density $\delta \rho$. Using the equation of hydrostatic equilibrium, the relation between the variations in pressure and radius is given by

$$\frac{\delta P}{P} = -4 \frac{\delta r}{r}. \quad (23)$$

The equation of mass conservation leads to the following relation between the variation in density and radius:

$$\frac{\delta \rho}{\rho} = -3 \frac{\delta r}{r}. \quad (24)$$

Combining these equations, we obtain the relation between the variations in pressure and density:

$$d \ln P = \frac{4}{3} d \ln \rho. \quad (25)$$

We then use the general form of the equation of state

$$d \ln \rho = \alpha d \ln P - \delta d \ln T, \quad (26)$$

with $\alpha = \left(\frac{\partial \ln \rho}{\partial \ln P}\right)_T$ and $\delta = -\left(\frac{\partial \ln \rho}{\partial \ln T}\right)_P$ to obtain the relation between the variations in temperature and density:

$$d \ln T = \frac{4\alpha - 3}{3\delta} d \ln \rho. \quad (27)$$

This relation between the changes in temperature and density during a slow contraction is sensitive to the equation of state of the stellar matter through the coefficients α and δ . For a perfect gas, $\alpha = \delta = 1$, and this relation simply gives

$$d \ln T = \frac{1}{3} d \ln \rho. \quad (28)$$

This means that during a slow contraction in nondegenerate conditions, the star evolves along a straight line with a slope of one-third in the diagram showing the variation of the central values of $\log T$ versus $\log \rho$. This situation approximately applies during the contraction of the star on a Kelvin-Helmholtz timescale before the ignition of hydrogen and also between the main nuclear burning phases when gravitational contraction provides the needed energy.

It is interesting to note that a slope of one-third in the $\log T_c$ versus $\log \rho_c$ diagram implies that the star can enter the domain of degenerate matter during its evolution. Indeed, the frontier between nondegenerate and degenerate conditions is defined by a straight line with a slope of two-thirds. This can be readily understood by recalling that for a completely degenerate non-relativistic gas, degenerate electronic pressure is related to density of $P < \rho^{5/3}$. Since $P < \rho T$ for a perfect gas, we then obtain $\rho T < \rho^{5/3}$ and hence $T < \rho^{2/3}$ when the perfect gas pressure of electrons equals the degenerate pressure. When a star approaches the domain of complete electron degeneracy, the values of the coefficients α and δ tend to 3/5 and 0, respectively. During this transition, α becomes therefore smaller than four-thirds before δ equals 0, so that the coefficient relating the density to the temperature variation in Eq. 27 above becomes negative. For a star entering the degenerate domain, a contraction does not produce an increase in the

temperature as in the nondegenerate case, but can instead result in a cooling of the stellar matter.

The effects of nuclear reactions are also completely different in degenerate conditions. Contrary to the nondegenerate case, an excess of energy production in the stellar center will not result in an expansion of the star when the matter is degenerate. In this case, an increase in temperature occurs in the center, but this increase does not produce a corresponding increase in the central pressure, which is solely determined by density in degenerate conditions. Consequently, nuclear reaction rates increase further and produce more and more energy, leading to a flash or an explosion. While nuclear reactions are stable in nondegenerate conditions, they are thus found to be unstable in degenerate conditions.

Applications

By numerically solving the equations of stellar structure derived above, the evolution of the internal and global properties of stars is obtained. This evolution can be quite different depending on the initial mass and chemical composition of the star. The evolutionary tracks in the theoretical Hertzsprung-Russell (HR) diagram showing the variation of the luminosity of the star as a function of its temperature is given in Fig. 1 for stars with a solar chemical composition. Different evolutionary scenarios can be distinguished according to the initial stellar mass.

Substellar Objects

Objects with initial masses below about $0.08 M_\odot$ never reach the central temperature required for hydrogen-burning ignition. These objects enter the degenerate regime during their contraction phase, leading to further contraction and cooling of the central layers as explained above. They are the progenitors of brown dwarfs. Note that for masses larger than about $0.012 M_\odot$, deuterium burning occurs. This nuclear energy release is, however, not sufficient to compensate for the radiative energy losses, so that these objects continue to cool down.

Stellar Evolution,

Fig. 1 Evolutionary tracks in the HR diagram for stars with a solar chemical composition and mass between 1 solar mass and 60 times the solar mass

Stars in a Mass Range of $0.08\text{--}0.5\ M_{\odot}$

Stars with initial masses between about 0.08 and $0.5\ M_{\odot}$ enter the phase of hydrogen burning. During this main-sequence phase, the energy production is due to the release of nuclear binding energy by transforming four hydrogen nuclei into one helium nucleus. As briefly mentioned when estimating the typical timescale of nuclear energy production, this corresponds to a mass defect of about 0.7% , which is approximately ten times the energy that may be liberated by other fusion processes. This fusion can take place through two main series of reactions: the proton-proton chain (pp chain) and the **CNO cycle**. The pp chain is named after its first reaction, which requires two protons to form a deuterium nucleus ${}^2\text{H}$. The deuterium then reacts with another proton to form ${}^3\text{He}$. The formation of ${}^4\text{He}$ can be achieved through three different branches: pp1, pp2, and pp3. For the pp1 chain, two ${}^3\text{He}$ nuclei are needed to obtain ${}^4\text{He}$, while the other chains require that ${}^4\text{He}$ already exists. The relative frequency of the pp branches is sensitive to the temperature, density, and chemical composition of the stellar layers. Having larger temperature sensitivity than the pp1 chain, the pp2 and pp3 chains will then dominate when the temperature increases.

The CNO cycle is the second main series of reactions for hydrogen burning. In this case, isotopes of C, N, and O are needed to obtain ${}^4\text{He}$. The temperature sensitivity of the CNO cycle is much higher than for the pp chain. Consequently, the pp chain will dominate over the CNO cycle at low temperatures (for temperatures typically lower than about $15 \times 10^6\ \text{K}$), while it becomes negligible compared to the CNO cycle for higher temperatures. Thus, hydrogen burning will mainly occur through pp. chains for lower-mass stars (typically for stars with masses lower than about $1.5\ M_{\odot}$) and CNO cycle for more massive stars.

After hydrogen exhaustion, the helium core becomes electron degenerate before reaching a temperature sufficient for helium ignition. Consequently, these stars only go through the hydrogen-burning phase and end up as helium white dwarfs. The duration of the hydrogen-burning phase is much larger than the age of the Universe for these stars, which are still burning hydrogen in their core. The observed helium white dwarfs are thus thought to come from more massive progenitors whose evolution has been radically changed by belonging to close binary systems.

Stars with an Initial Mass Between About 0.5 and $2.3 M_{\odot}$

These stars enter both the hydrogen and the helium burning phases. During the main sequence, these stars exhibit small convective cores or no convective core (for masses smaller than about $1.2 M_{\odot}$). After central hydrogen exhaustion, there will be a transition from central hydrogen burning to hydrogen fusion in a shell surrounding the core, resulting in a slow increasing of the mass of the helium core. At this point, the temperature of the core is still far from being high enough for helium ignition: the star is in a phase of hydrogen shell burning. Together with the core contraction, there is an expansion of the hydrogen-rich envelope resulting in a shift in the HR diagram toward lower surface temperatures. The star then begins to ascend the [red giant](#) branch. The densities in the central layers are high enough for the electron gas to become degenerate. At the tip of the red giant branch, helium ignites in degenerate conditions, leading to a strong temperature rise within a very short time interval (of the order of the dynamic timescale) that is called the helium flash. This temperature rise stops when the temperature is high enough to lift the degeneracy of the electron gas. The helium flash removes therefore the degeneracy in the stellar core and enables the helium-burning phase to continue in nondegenerate conditions.

Helium burning requires temperatures higher than about 10^8 K. The fundamental reaction at the basis of the formation of ^{12}C from three ^4He nuclei is the triple alpha reaction. Note that the star is not totally disrupted by the helium flash, since the massive shell surrounding the helium zone is able to damp the explosive shock wave produced in the internal layers. After the helium flash, the star finds a new equilibrium configuration either on the horizontal branch in the HR diagram (at low metallicity) or on the so-called red clump (at solar and higher metallicity) where core helium burning takes place. After the helium-burning phase, the star evolves along the asymptotic giant branch (AGB) until the outer envelope is removed by wind and thermal pulses, and a planetary nebula forms around the white dwarf.

Stars with an Initial Mass Between About 2.3 and $10 M_{\odot}$

The beginning of the evolution of stars with an initial mass in the mass range of $2.3\text{--}10 M_{\odot}$ is similar to the evolution of lower-mass stars undergoing a helium flash. Their evolution differs after the exhaustion of hydrogen in the central stellar core. This difference is mainly due to the fact that hydrogen burning for these more massive stars occurs in well-mixed convective cores leading to a helium core with a nonnegligible mass at the end of the main sequence. Due to the absence of a central energy source, the helium core tends to become isothermal, while hydrogen shell burning occurs at the bottom of the surrounding hydrogen-rich envelope. The star then rapidly crosses the HR diagram to become a red giant. The contraction of the core proceeds approximately on a Kelvin-Helmholtz timescale, and goes with an expansion of the hydrogen-rich envelope. The core contraction occurs in nondegenerate conditions resulting in the heating of the central layers. The central temperature rises until it reaches the temperature required to ignite helium (about 10^8 K). This results in a new source of central energy that stops the rapid contraction of the core: the star is then again in a phase of complete equilibrium, which terminates when ^4He is entirely transformed into ^{12}C , ^{16}O , and ^{20}Ne . Stars with initial masses below about $8 M_{\odot}$ evolve along the asymptotic giant branch and experience a prolonged phase of thermal pulses leading to the ejection of the envelope and the formation of a carbon-oxygen white dwarf, as in the case of the lower mass stars experiencing the helium flash.

For stars with initial masses between approximately 8 and $10 M_{\odot}$, the situation is more complex. Indeed, the evolution depends on the competition between the changes of temperature and densities in the central layers, which can reach values required for carbon ignition, and the efficiency of mass loss at the stellar surface, which can remove the envelope. This evolution will then depend on three key mass limits: the maximum initial mass that leads to the formation of a white dwarf, the maximum initial mass that leads to a collapse by electron capture, and the minimum

initial mass that leads to a non-explosive carbon ignition in the core. From a theoretical point of view, the main difficulty relies on the fact that these mass limits are close to each other and are sensitive to many physical ingredients adopted in the models, as the mass loss rates, or the modeling of convection. A plausible scenario is that the mass limit that leads to a non-explosive carbon ignition in the core is lower than the mass limit that leads to a white dwarf that is itself lower than the mass limit leading to a collapse by electron capture. In this case, an oxygen-neon white dwarf would be obtained for stars with initial masses between about 8 and 9 $M_{\odot}$, electron capture supernovae would occur for stars between about 9 and 10 $M_{\odot}$, and core collapse supernovae will occur for more massive stars.

Massive Stars

Massive stars can be simply defined as stars that go through all nuclear burning phases: hydrogen, helium, carbon, neon, oxygen, and silicon burning. The minimum initial mass for a star to proceed through this whole sequence of nuclear phases is approximately of 10 $M_{\odot}$. This series of nuclear burning phases comes to an end with the formation of an iron core since no further exothermic fusions are then possible. The evolution of the central layers of these stars can be simply viewed as following succeeding cycles of nuclear burning, exhaustion of nuclear fuel, core contraction, and heating enabling the ignition of the next burning phase. As a result of these succeeding evolution cycles, heavier elements gradually accumulate near the center of the star. This leads to the characteristic “onion-skin structure” of the interior of evolved massive stars, where heavier elements are present on separated mass shells as the distance to the stellar center decreases.

Mass loss plays a major role in the evolution of massive stars. Indeed, these stars are characterized by a high temperature-to-density ratio resulting in a high radiation-to-gas pressure ratio, which favors mass loss by ► [stellar winds](#). Wolf-Rayet stars nicely illustrate the effects of mass loss on massive stars. These stars exhibit high mass loss rates and strong emission lines with highly nonsolar chemical abundances. The abundance of anomalies

observed on the surface of Wolf-Rayet stars clearly indicates that a mechanism is able to efficiently remove the surface layers of the star. This can either be done through stellar wind losses in single stars, or through Roche lobe overflow in binary systems.

Massive stars end their lives in supernovae explosions, enriching the interstellar medium with processed material and leaving a neutron star or a black hole as a remnant, depending on the mass of their iron core. When the mass of the core exceeds the so-called Oppenheimer-Volkoff mass (around 2 $M_{\odot}$), a black hole is formed. Otherwise, the pressure of degenerate neutrons is able to stop the collapse and lead to the formation of a neutron star.

Future Directions

The classical view of stellar evolution described above is based on many simplifying hypotheses: stars are considered as spherical systems in hydrostatic and radiative equilibrium, where mixing only occurs in convective zones. In particular, the effects of rotation and magnetic fields are neglected. This classical theoretical description correctly accounts for many astronomical observations. However, with the increasing amount of observational data, quantitative discrepancies appear between observations and theoretical predictions of standard models. For instance, standard stellar models are unable to reproduce neither the observed abundance anomalies of helium and nitrogen at the surface of massive stars nor the observations of light element abundances at the surface of solar-type stars. This suggests that other transport mechanisms take place in stellar radiative zones. Rotation is one of the key physical processes that have a deep influence on all aspects of stellar structure and evolution. The effects of magnetic fields on the internal stellar structure need also to be taken into account to obtain a coherent picture of stellar evolution. Consequently, various theoretical models of these physical processes have been developed and compared to observational data in order to make progress in our understanding of stellar physics. These comparisons are, however, somewhat limited by the

fact that classical astronomical observations only give us access to properties of the surface of the star, such as the effective temperature, luminosity, and surface chemical composition. Indeed, the opacity of a star is so large that only a tiny layer surrounding the star, the photosphere, can be observed. This is insufficient to compare and constrain a whole theoretical structure of the stellar interior, where complex physical processes are taking place. Obtaining direct observational constraints on the internal properties of stars is thus required. In this context, the rapidly developing field of ► [asteroseismology](#) offers a valuable opportunity to make significant progress in our understanding of stellar structure and evolution.

We finally note that the evolution of binary stars can be quite different from the classical single-star evolutionary scenarios briefly described above. All physical processes discussed here for single stars also apply to binary stars but with a higher degree of complexity due to possible mass transfers, tidal interaction and mixing, tidal generation of gravity waves, etc.

Keywords

Galaxies · Initial mass function · Metallicity · Stars · Stellar evolution

Acronyms

Pop Population

Definition

Astronomers use the terms Populations I, II, and III to refer to groups of stars whose mass fraction

of elements heavier than helium is similar to the Sun (Population I), much less than the Sun (Population II), or negligible (Population III, not yet observed but hypothesized to be the earliest generation of stars). In general, stars with greater abundances of heavier elements are younger than those with lower abundances.

Overview

One of the more common classifications of stellar populations is based on age and metallicity, where metallicity is the proportion of the stellar mass made up of chemical elements other than hydrogen and helium. In that classification, the stars are divided into Populations I, II, or III. The stellar populations show a continuum of properties, and it is difficult to place some stars in a given population.

Population III stars are hypothesized to be the first ones formed in the Universe when the composing gas was only H and He. Since no stars of zero metallicity have been observed yet, the vast majority of these stars would have had high masses, in other words, they followed a different initial mass function compared to the present one.

When the most massive of those stars exploded as supernovae, they ejected heavy chemical elements into the interstellar medium where subsequently the very metal-poor Population II stars formed. By combining data from different ongoing and future surveys, it will shed light on the very metal-poor stars, and consequently about Population III.

Population II stars are mainly located in the halo of the Milky Way, in most globular clusters and dwarf galaxies with no gas. These stars are older than about 10 Gyr and have metallicities between 0.001% and 10% of the solar value.

Population I stars are located on the disk; these stars are the youngest of the galaxy and show metallicities between about one-tenth and three times the solar value. All observed stars with planetary systems, including the Sun, are Population I stars, and the stars with metallicities

higher than the solar one show a trend to harbor giant planets.

There are some stars that do not follow these rules: (1) elliptical galaxies, bulges, and the inner disk of spiral galaxies show metal-rich stars that are older than 10 Gyr; and (2) dwarf irregular galaxies and the outer disk of spiral galaxies show metal-poor stars that are younger than 1 Gyr.

Another common classification of stellar populations is based on the photometric properties: stellar groups dominated by blue stars are called early-type populations, and those dominated by red stars are called late-type populations. Yet another concept of stellar population is commonly used in the evolution of stellar groups, like a galaxy or a galactic component, is the Simple Stellar Population (SSP). In an SSP, all stars have the same age and the same metallicity; in addition, they are born in the same region of space. Since a galaxy is formed by diverse types of stars, a galaxy can be studied as a combination of SSPs of different ages, metallicities, and masses. Therefore, the SSPs allow observational astronomers to infer the age, the metallicity, and the mass of the stars that shine in a galaxy.

Stellar Pulsation

Patrick Eggenberger
Geneva Observatory, University of Geneva,
Geneva, Switzerland

Synonyms

[Stellar oscillation](#)

Definition

Stellar pulsations or oscillations are periodic variations of the size, brightness, and temperature of the star induced by some internal physical processes. These pulsations can be either radial, with symmetric expansions and contractions over the whole stellar surface, or non-radial when the spherical symmetry of the star is not preserved. Stellar pulsations provide us with a valuable opportunity to study the internal properties of stars that are not accessible otherwise and to obtain a cosmic distance scale by calibrating the luminosity of stars with their pulsation periods.

Stellar Rotation

Sylvia Ekström
Département d'astronomie de l'Université de
Genève, Faculté des Sciences, Versoix,
Switzerland

Keywords

Stellar evolution · Mixing · Nucleosynthesis ·
Supernova · Spectral type · Absorption lines

Definition

The fact that a star rotates induces changes in its evolution. The centrifugal force brings an additional component which adds to pressure in sustaining the star against its own gravity. Rotation induces instabilities which in turn induce mixing. The mixing leads to larger cores and longer life-time and also modifies the nucleosynthesis. For the most massive stars, fast rotation can modify the dynamics of the final supernova, breaking the spherical symmetry during the collapse. From an observational point of view, rotation modifies the spectral type and luminosity class inferred for the star. It also widens the absorption lines, because of the differing Doppler velocity of the approaching versus the receding side of the star.

Overview

Roughly summarized, a star is a sphere of ionized gas held in hydrostatic equilibrium by the competition between gravitation and pressure. Any additional force will modify the equilibrium and thus the characteristics of the object. Rotation brings such an additional force.

During star formation, a molecular cloud with a typical radius of 0.1 pc contracts to form a newborn star with a reduction of radius through six orders of magnitude. Angular momentum conservation implies that the slightest rotation movement in the cloud will convert into fast stellar spin. It is not yet clear how the excess angular momentum is driven away so that the star can actually form, probably through magnetic interactions between the star and the protoplanetary disk or through the formation of binary stars, where angular momentum is transformed into orbital motion.

If the angular momentum kept by the young star is high enough, the centrifugal force that it experiences becomes nonnegligible and adds a sustaining force against gravity (see Fig. 1). At the very beginning of its evolution, the star behaves as if its mass were smaller: the luminosity and effective temperature are shifted to lower values. As the evolution proceeds, rotation

Stellar Rotation,

Fig. 1 Maximal surface deformation of a rotating star. (Courtesy C. Georgy). The x and y axis are the radius, normalized to the polar one. The gravitational force is in black, the centrifugal force in red, and the resulting effective gravity in blue

triggers various instabilities inside the star, among which:

- The *shear instability*: As the star does not rotate like a rigid body, the differential rotation induces a shear between layers with different angular velocities. The shear drives a turbulent mixing of the chemical species through the different layers.
- The *Eddington-Sweet circulation*: Rotation deforms the star (Fig. 2), so except at the equator, the centrifugal force is not parallel to gravity – the resultant effective gravity is not radial, as shown in Fig. 1. The radiative flux, which depends on the local effective gravity, is not constant on equipotential surfaces. According to von Zeipel (1924), the star cannot be in hydrostatic and radiative equilibrium at the same time. This drives a large-scale current, also known as the *meridional circulation*, which mainly transports the angular momentum inside the star.

The main observable characteristics of the star (effective temperature, gravity, luminous flux) become colatitude-dependent, feature which can now be observed by interferometric techniques (Domiciano de Souza et al. 2003).

The shear mixing brings fresh hydrogen into the burning core which grows, enhancing the luminosity of the star. Since more fuel is available, the duration of the main sequence is increased.

Rotation enhances the mass loss by radiative winds through three mechanisms:

- The stronger effective gravity at the poles induces a stronger flux in that direction.
- The lower effective temperature at the equator increases the opacity and thus the atomic line-driven winds.
- Later during core He burning, rotational mixing brings freshly synthesized heavy elements to the surface, increasing the effective metallicity of the star.

Generally, rotation favors a redward evolution in the HR diagram. Its inclusion in stellar evolution codes has improved the match between models and observations in many aspects, as the evolution of the surface abundances during the main sequence (Heger and Langer 2000; Maeder and Meynet 2000), the variation with metallicity of the red-to-blue supergiant ratio (Maeder and Meynet 2001), and the Wolf-Rayet to O-type stars ratio (Meynet and Maeder 2003; Vink and de Koter 2005).

Shear mixing induces a transport of elements between the burning core and the burning shells, modifying the nucleosynthesis. For example, the transformation of carbon produced in the He-burning core into nitrogen in the H-burning shell is supposed to be the origin of the primary nitrogen observed at very low metallicity (Meynet and Maeder 2002).

Stellar Rotation, Fig. 2 *Right* – deformation of the surface of $20 M_{\text{sol}}$ rotating stellar models. The curves show increasing (from black to red) ratios of the angular velocity to the critical one, which is the angular velocity at which the outer layers of the star are no more gravitationally bound. At critical velocity, the equatorial radius is 1.5

times the polar one. *Left* – effective temperature as a function of the colatitude (pole, $\theta = 0^{\circ}$; equator, $\theta = 90^{\circ}$) for the same models. Fast rotation leads to hotter poles and cooler equator, the difference amounting to a factor of 2 at critical rotation. (From Ekström et al. (2008))

Asteroseismic observations of the internal rotation of red giants and subgiants (Beck et al. 2012; Deheuvels et al. 2014) have shown that the differential rotation between the core and the envelope is less pronounced than expected by models during this phase of rapid core contraction and envelope expansion. This points to an additional angular momentum transport mechanism being needed in models (Eggenberger et al. 2012). The source of this mechanism is not yet identified.

By modifying the geometry of the explosion, rotation influences strongly the supernova dynamics. It is thought that the collapse of a rapidly rotating massive star is at the origin of the long-duration Gamma-ray bursts (Woosley 1993; Woosley and Bloom 2006).

Stellar Winds

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Keywords

Young star · High mass star

Definition

The tenuous outer layers of stars can be driven off into space, creating the flows known as stellar winds. In main-sequence stars like the Sun, the winds are driven by thermal pressure in the hot stellar corona. The wind, being guided by the star's magnetic field, is anisotropic. More massive stars and red giants propel gas by radiation pressure. Young stars have especially vigorous winds that are responsible for dissipating ambient cloud gas and circumstellar disks, thus ending planet formation. Here, gas is believed

to be flung out centrifugally along magnetic field lines embedded in the star and its surrounding disk.

Overview

Stars of all masses and all evolutionary phases slough off their outermost layers of gas. The resulting, low-density flow is known as a stellar wind. The most familiar example is the solar wind, which has been extensively studied by satellites and other spacecraft for half a century. Ionized gas from the Sun flows past the Earth at an average speed of 500 km/s. Some ions become trapped in the Earth's magnetic field, creating the auroral glow seen near both the north and south poles.

The solar wind is driven by the pressure of very hot gas of several million degrees at the base of the Sun's corona. Other main-sequence stars with the Sun's mass and below are thought to generate similar winds. The most massive winds from main-sequence objects are produced by O stars, which also have the highest luminosity. These winds are driven by the radiation pressure from ultraviolet photons acting on ionized gas in the stellar atmosphere. The gas piles up periodically and creates internal shocks, which are detected by the X-rays they emit.

Aging stars that have left the main sequence also attain large luminosities and emit relatively massive winds. Here, the driving force is radiation pressure from infrared photons. The pressure is exerted not on the gas itself, but on dust grains that condense in the flow. Indeed, dust grains throughout interstellar space ultimately arise from nucleation within the winds of red giants.

Young stars, even those of low mass, produce vigorous stellar winds. The winds from classical ► [T Tauri stars](#) are seen by characteristic P Cygni line profiles in the stellar atmosphere and by spatially extended jets. These stars have strong magnetic fields and also rotate relatively fast. Accordingly, the winds are driven by material being flung out along magnetic field lines. The field is anchored in the stellar surface and the innermost region of its circumstellar disk. Similar

winds of even greater strength must arise from embedded protostars.

Whatever their origin, the winds from young stars play a fundamental role in star and planet evolution. Those emitted by protostars dissipate the surrounding molecular clouds, thus ending the accretion of gas and revealing the star optically. Winds from ► [pre-main-sequence stars](#) are responsible for driving off their circumstellar disks, terminating the process of planet formation.

Stellar Yield

Nikos Prantzos
Institut d'Astrophysique de Paris, Paris, France

Definition

The mass of nuclides ejected by a star into the interstellar medium, at the end of or during its life (through the final explosion or its wind, respectively) may be called the stellar yield. For instance, a star of $\sim 20 M_{\odot}$ ejects $\sim 1 M_{\odot}$ of oxygen. In general, lighter elements are produced during the hydrostatic evolution of the star, while heavier elements are produced by the final explosive nucleosynthesis. The *net* stellar yield is the

difference between that quantity and the amount of the nuclide incorporated in the star at its formation (i.e., the amount of newly synthesized nuclei) and contributes to the chemical evolution of the galaxy. Stellar yields depend on the mass of the star but also on its initial ► [metallicity](#), mass loss, rotation, etc. They are theoretically calculated but rarely validated by observations (the only case being supernova SN1987A, a 18–20 $M_{\odot}$ star, which produced 0.07 $M_{\odot}$ of ^{56}Fe , as inferred from the evolution of its luminosity).

Definition

Steranes is a class of four-ringed cyclic compounds derived from steroids or sterols via diagenetic degradation and thermal maturation. The sterane structure is fully saturated with hydrogen atoms (Fig. 1) and makes up the hydrocarbon core of all steroids

Steranes, Rock Record,

Fig. 1 Core structure of steranes composed of C–C bonds (lines) and saturated with hydrogen atoms (not shown). The key stereochemical variants occur at C-5, C-14, C-17, and C-20 positions. Additional methylation is common at C-2, C-3, C-24, and C-23. R = H, methyl, ethyl, *n*-propyl, and isopropyl groups

and sterols. Steranes are often regarded as molecular fossils of eukaryotic organisms, particularly those having a side chain at the C-24 position.

Overview

The precursor compounds of steranes, steroids and sterols, are essential lipids for maintaining rigidity and permeability of membranes in all eukaryotes. Steroids are isoprenoids and synthesized from squalene in complex biosynthesis in which multiple steps require reactions with molecular oxygen.

Most variations in steroid structures (i.e., position and number of double bonds, hydroxyl groups, and other functional groups) are lost during the diagenesis and thermal maturation. However, structural variants with alkyl side chains are preserved over geological time-scale in bitumen and oils and as constituents in kerogen of Cenozoic to Archean rocks. Although most sterol structures are widespread among eukaryotes, some alkylated structures are specific to particular taxonomic groups (e.g., sponges and algal groups) and may be distinguishable in the molecular fossil record as different steranes. Oftentimes, individual steranes may be produced by members outside of the proposed taxonomic group and so further investigation of compound abundance or ratio to related compounds must be undertaken prior to source inference.

Steranes and their precursors exist as three-dimensional structures. Despite the 100s of possible stereochemical variations in the structures, steroid biomolecules are very specific (especially at C-5, C-14, C-17, and C-20 positions). Steroid and sterol stereochemistry is regarded as a classic example of stereochemical specificity of biomolecules in general – a fundamental biosignature of life. During diagenesis and thermal maturation, the specific biomolecular stereochemistry is lost and other isomers are formed. The relative abundances of some sterane isomers are commonly used to indicate particular geological or thermal conditions.

Most molecular fossils including steranes are thermally released from kerogen in ancient rocks, either naturally to form bitumen and oil or artificially in the laboratory. Sterane precursors are typically bound to the kerogen matrix through weaker C–O and C–S bonds resulting in their early release during thermal alteration. The sterane composition of bitumen and oils is typically determined by extracting hydrocarbons from rock or directly from oil using a nonpolar organic solvent (such as hexanes) and then analyzed via gas chromatography mass spectrometry instrumentation.

Stereochemistry

Gilles Bruylants
Engineering of Molecular NanoSystems,
Université Libre de Bruxelles, Brussels, Belgium

Definition

Stereochemistry refers to the relative spatial arrangement of atoms within molecules. Also

known as 3D chemistry, it spans the entire range of organic, inorganic, biological, physical, and supramolecular chemistries. Stereochemistry focuses on ► [stereoisomers](#), molecules that have the same chemical formula and in which the atoms have the same connectivity but different spatial distributions. If two stereoisomers are mirror images of each other, they are called ► [enantiomers](#). If they are non-mirror images of each other, they are diastereoisomers.

Stereoisomers

Robert Hazen
Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC, USA

Keywords

Chiral pairs of molecules · Enantiomeric pairs of molecules · Mirror symmetric pairs of molecules

Synonyms

[Stereoisomers](#)

Definition

Stereoisomers are molecular ► [isomers](#), in which two or more molecules have identical molecular formulas and atomic connectivities, but in which the atoms are arranged differently in space. Stereoisomers thus contrast with constitutional

isomers, which have identical molecular formulas but differing atomic connectivities.

Stereoisomers are divided into two important groups. Conformational isomers are interchangeable by a rotation around a single bond. By contrast, configurational isomers are not readily transformable from one to the other; bonds must be broken to achieve such a transformation.

Configurational isomers are further subdivided into enantiomers (mirror image pairs of molecules) and diastereomers (which are not related by mirror symmetry). ► [Enantiomers](#), unlike diastereomers, display many identical properties, including density, vapor pressure, melting and boiling points, and other thermochemical properties.

Institute of Technology, Meguro-ku, Tokyo,
Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

In chemistry, a steric effect is an influence on a reaction's course or rate determined by the fact that all of the atoms within a molecule occupy space; thus, certain collision paths are either

disfavored or favored. When atoms are brought close together, there is an associated cost in energy due to overlapping electron clouds, and this may affect the molecule's preferred conformation and reactivity. Steric effects are frequently contrasted with electronic effects in explaining chemical reactivity. Steric effects can play a significant role in ► [molecular recognition](#).

Stirling Range Biota

Stefan Bengtson
Department of Palaeozoology, The Swedish
Museum of Natural History, Stockholm, Sweden

Keywords

Eukaryotes · Multicellular · Paleoproterozoic ·
Trace fossils

Definition

The Stirling Range biota is a Paleoproterozoic biota found in the Stirling Range formation of southwestern Australia and composed of disk-shaped fossils and trace-making organisms about 1.8–2.0 Ga old. The biota lived in a near-shore

marine environment and is thought to have included motile multicellular eukaryotes.

Overview

The Stirling fossils were discovered in southwestern Australia in the 1990s and were interpreted to represent metazoans (animals) belonging to the Ediacaran biota, less than 600 Ma old (Cruse and Harris 1994; Cruse et al. 1993). Subsequent radiometric dating of the sandstones containing the fossils showed that the Stirling Range biota is considerably older than the Ediacaran, between 1.8 and 2.0 Ga old (Rasmussen et al. 2004).

The biota contains disk-shaped fossils of unknown affinities (Fig. 1) and paired ridges interpreted as traces of moving organisms

Stirling Range Biota, Fig. 1 Discoidal fossil of uncertain affinity. (From Bengtson et al. 2007)

(Fig. 2). The traces have a characteristic hairpin shape, with one end closed and the other end usually slightly flaring. The tracemaker has been reconstructed as a motile multicellular or syncytial/multinucleate eukaryotic organism of unknown affinity (Bengtson et al. 2007; Rasmussen et al. 2002). The organism probably had a bulbous resting shape but stretched out into a more elongate body form, 1–2 mm in width, when in motion. Moving along the sea floor, the organism left sediment-entrained mucus ridges behind on both sides. The occasional presence of ridge pairs with crossed-over ridges suggests that the ridges represented two sides of a coherent band and that the organism laid down a string of mucus as it was crawling, much like today's ribbon worms or garden snails.

Because of its considerable age, more than three times that of the earliest uncontroversial trace fossils - made by metazoans - in the rock record, the interpretation of the Stirling structures as traces of moving organisms has been questioned (Budd and Jensen 2003; Conway Morris 2002; Seilacher 2007). No tenable alternative interpretation has yet been offered; however, a recent discovery of giant amoebas making similar traces on modern sea floors off the Bahamas has confirmed that other organisms than metazoans are able to make such traces (Bengtson and Rasmussen 2009; Matz et al. 2008).

The Stirling Range biota, if correctly interpreted, represents early experiments into the energy-craving life mode of motile multicellular organisms. The question why it took more than a billion years before the multicellular life forms became an important component of the biosphere has yet to be convincingly answered but may be connected to the fluctuating oxygen levels of the ancient atmosphere.

Stirling Range, Australia

Stefan Bengtson

Department of Palaeozoology, The Swedish Museum of Natural History, Stockholm, Sweden

Definition

The Stirling Range is a 60-km long range of hills in southwestern Australia, about 330 km SE of Perth. It is built up of a ca 1.6 km thick Paleoproterozoic sequence of siliciclastic sediments, the Stirling Range Formation. The sediments, mostly sandstones and shales, were deposited between

1.8 and 2 Ga ago along an ocean-facing shoreline influenced by storms, long-shore currents, and tidal currents. The rocks were subjected to low-grade metamorphism about 1.2 Ga ago. The Stirling Range Formation houses a fossil biota of disk-shaped and trace-making organisms, the ► [Stirling Range Biota](#).

[Artificial meteorite](#)

Definition

STONE is a series of experiments to test the survivability of terrestrial sedimentary rocks, analogues of Martian sediments, embedded in the heat shields of Foton capsules during entry into the Earth's atmosphere at a velocity of 7.6 km/s (meteoritic entry speeds being higher at

12–15 km/s). At the same time, the ► [panspermia](#) hypothesis was tested with live endolithic microorganisms protected by 1–2 cm of rock thickness, as well as the survival of organic and morphological biosignatures encapsulated within the sediment. A dolomite, a siltstone, a volcanic sandstone, and a ► [basalt](#) control sample survived entry into the atmosphere, as did organic and morphological biosignatures away from the fusion crust. The ► [endolithic](#) microorganisms did not survive.

Overview

Of six STONE experiments, only three were successfully carried to completion. STONE-1 flown in 1999 tested a basalt (in flight control), a dolomite (sedimentary rock), and artificial Martian regolith. Only the dolomite sample survived, having lost 70% of its original thickness. Some kinetic isotopic fractionation accompanied the thermal degradation of the dolomite during reentry (Brack et al. [2002](#)). STONE-5, 2005, carried dolerite (an igneous rock), sandstone (a sedimentary rock), and gneissic impactite from Haughton Crater that were loaded with bacterial *Bacillus subtilis* spores, fungal *Ulocladium atrum* spores, and photosynthetic endolithic cyanobacteria *Chroococcidiopsis* sp. Despite intense ablation resulting in deeply eroded samples, all rocks in part survived atmospheric reentry. Temperatures attained during reentry were high enough to form fusion crusts on the exposed gneiss and dolerite surface, thus strengthening the link with real meteorites. None of the microorganisms survived, and it was concluded that atmospheric transit acts as a strong biogeographical filter to the interplanetary transfer of photosynthetic microorganisms (Brandstätter et al. [2008](#); Cockell et al. [2007](#)). STONE-6, 2007, tested a silicified volcanic sand, 3.446 ga old, containing cryptic traces of fossil life (Westall et al. [2006](#)), a Devonian mudstone containing organic biomarkers, and an Eocene basalt from Austria. The basalt was lost but the two sedimentary rocks survived, severely ablated. Mineralogical changes

indicated that entry temperatures exceeded $\sim 1800^\circ\text{C}$ that resulted in the fusion of both sediments. The 3.446-Ga-old microfossils survived furthest from the fusion crust while the organic carbon in the Devonian laminite sample was altered and thermally matured. Dried biofilms of *Chroococcidiopsis* pasted onto the underside of the rocks did not retain viability although the cells survived in a carbonized form (Foucher et al. 2010).

Although the speed of entry of these artificial meteorites was not as high as that of natural meteorites, 7.6 km/s as opposed to 12–15 km/s, it was close enough to produce fusion crusts on some of the sediments and to provide useful information relating to potential Martian sedimentary meteorites. Martian rocks having compositions typical of the terrestrial sediments tested could arrive on Earth as meteorites, providing they survive impact escape from Mars. Organic and morphological biosignatures in the Martian rocks could also survive. Heat flux calculations in the 3.446-Ga-old volcanic sand indicate that at least 5 cm rock thickness is necessary to protect extant organisms from heat shock.

Stratigraphy

Felix M. Gradstein
University of Oslo, Oslo, Norway

Keywords

Correlation · Fossils · Geochronology · Geological strata · Sedimentary rocks

Definition

Stratigraphy is the scientific discipline dealing with the nature, relative order, and physical and paleontological content of the rock record on Earth. Stratigraphy (“description of strata”), like most geologic sciences, is essentially a natural philosophy rooted in a body of organized cumulative observations, governed by a series of accepted principles and rules, and has three main attributes: (1) The irreversible flow of time, often called the arrow of time; (2) superposition of successively younger strata, often referred to as Steno’s law, after the seventeenth century Danish scientist Nicholas Steno who first formulated this principle from observation in the hills of Italy;

(3) the evidence of events as fossilized in Earth's sedimentary record, and their spatial and temporal relations.

Overview

Correlation of the rock record plays a major role in stratigraphy. To the geologist such correlation often requires the hypothesis that correlated units have the same age. Without correlation, the rock record and its succession in time derived in a single area are unique, and contribute nothing to understanding the Earth history elsewhere. Stratigraphy has developed several main components or subdisciplines, each with their own scientific specialists (Rawson et al. 2002; Rey and Galeotti 2008): Lithostratigraphy, biostratigraphy, chronostratigraphy, magnetostratigraphy, cyclostratigraphy, organic and inorganic isotopic chemostratigraphy, and, in the subsurface, seismostratigraphy and well-log stratigraphy. Seismostratigraphy is a special type of lithostratigraphy using acoustic remote sensing and visualization; well-log stratigraphy uses specialized tools to record down-hole physical and chemical properties. All stratigraphies strive to assign (often unique) attributes to an individual rock unit that makes it distinguishable from lateral, underlying or overlying rock units, and thus assist with its correlation. When properly stacked, described, and correlated, the rock record in sedimentary basins, flat or hilly landscapes, and mountain ranges may thus reveal their history through geologic time.

Stratosphere

Sébastien Lebonnois

Laboratoire de Météorologie Dynamique (LMD/IPSL), Sorbonne Université, CNRS, Paris, France

Definition

In this region, as in the mesosphere (located above), the dominant mode of energy transfer is radiation, with a balance between the energy absorbed from the stellar irradiation by gaseous components and particles when present, and the energy reemitted by these components at infrared wavelengths. This balance in these regions is characterized by local thermodynamic equilibrium, which means that the energy distributions of the molecules are in equilibrium and follow the Boltzmann distribution.

The stratosphere starts above the tropopause and is characterized by an increase of temperature with altitude, a region that is not always present in the vertical structure of an atmosphere: no stratosphere are present in the atmospheres of Venus and Mars. This is due to a source of energy absorption. In the Earth atmosphere, heating is due to absorption of solar light by ozone molecules. For giant planets, it is due to methane, while in the atmosphere of Titan, the photochemical haze particles play a significant role in this heating. This positive temperature gradient is associated with a strong stability of the atmosphere, inhibiting vertical exchanges between atmospheric layers.

The upper boundary of the stratosphere is called the stratopause (at roughly 50 km altitude for the Earth).

Definition

Microbial biomass naturally transits through the Earth's ► [stratosphere](#) (roughly 12–50 km above the surface), a deadly environment sharing many conditions also present on the surface of ► [Mars](#), including cold temperatures, severe dryness, and strong solar radiation. To collect samples at extreme altitude and perform controlled exposure experiments in this ► [Mars](#) analogue site, investigators use mountaintop observatories, aircraft, and scientific balloons.

Overview

Earth's ► [stratosphere](#) is located approximately 12–50 km above the surface (depending on location and season) and is practically at the edge of space. At these extreme altitudes, atmospheric pressure is comparable to surface conditions on ► [Mars](#) (about 0.1–1 kPa), alongside ultralow temperatures (0–100 °C), intense ► [desiccation](#), and ► [extreme ultraviolet light](#) (~50 W·m²); the stratosphere is a compelling analogue for the Red Planet (Smith 2013; Smith and Sowa 2017).

Microbial ► [life](#) emanating from the Earth's surface (collectively known as *bioaerosols*) can reach stratospheric heights through strong convective forces such as thunderstorms, monsoons, and hurricanes (Griffin et al. 2017). Stratospheric intrusions also occur regularly alongside mountain ranges. Reaching the stratosphere is more probable for smaller bioaerosols (<1 µm), and particle size determines total residence time aloft. Although it is unknown how long ► [micro-organisms](#) can stay airborne in the Earth's stratosphere, non-biological ► [aerosols](#) (e.g., volcanic ash) can potentially remain drifting through the upper atmosphere for years before returning to the surface (Smith 2013).

Generally, the diversity of microbial taxa measured in the lower stratosphere matches proportional abundances found in surface and marine/freshwater environments; however, the concentration of biomass in the upper atmosphere is orders of magnitude lower (Smith et al. 2013). Since cold temperatures and severe dryness inhibit metabolic activities, microorganisms pass through the stratosphere in a state of dormancy. Yet, remarkably, viable microbes have been collected at stratospheric altitudes ranging from 12 to 41 km (Smith et al. 2009, 2018; Wainwright et al. 2003), with most surviving isolates captured as bacterial ► [endospores](#) specially adapted for dispersal and resistance to environmental insults. Exactly how some terrestrial microorganisms withstand the harsh stratosphere remains an open question in the field of ► [aerobiology](#), but shading from sunlight provided by co-transported dust or biomass debris is a leading explanation. While viable ► [fungi](#) also appear in stratosphere surveys (Smith et al. 2009, 2013), ► [bacteria](#) probably represent the most common form of stratospheric biomass due to smaller sizes. Modern microbiological expeditions in the stratosphere now rely upon molecular measurements, including fluorescent microscopy- and ► [DNA sequencing](#)-based detection assays (Bryan et al. 2014; Smith et al. 2018). These molecular approaches have revealed a surprising richness of microorganisms in the stratosphere, previously masked by limitations associated with culture-based methods

Stratosphere Biology,

Fig. 1 A stratosphere biology experiment, *Exposing Microorganisms in the Stratosphere* (*E-MIST*), flown to 31 km by Khodadad et al. (2017) onboard a large ▶ [NASA](#) scientific balloon

and biocidal atmospheric conditions that render most collected biomass dead, damaged, or destroyed.

Teams acquiring microbiological samples can use mountaintop observatories (Smith et al. 2013) and aircraft (Smith et al. 2009, 2018) for routine lower stratosphere access, as well as meteorological (Bryan et al. 2014) and large scientific balloons (Wainwright et al. 2003) for less frequent middle and upper stratosphere access. Considering the fundamentally low concentration of biomass in the stratosphere, regardless of sampling technique used, investigators must carefully monitor contamination control methods (Smith 2013; Griffin et al. 2017).

Along similar lines of research, ▶ [astrobiology](#) teams studying the probability of terrestrial ▶ [exposed surface bioburden](#) surviving on Mars have intentionally sent spacecraft-associated microorganisms to the Earth's stratosphere onboard balloons for exposure-based experiments relevant to the field of ▶ [planetary protection](#) (Fig. 1) (DasSarma and DasSarma 2018; Khodadad et al. 2017; Smith and Sowa 2017). Results from stratosphere exposure investigations demonstrate the vulnerability of endospore-forming bacteria to intense short wavelength ▶ [ultraviolet radiation](#) levels (100–280 nm) and can provide predictive measurements for terrestrial microbes inadvertently delivered to Mars with spacecraft missions.

Strecker found that the amino acid alanine had been synthesized. This represented the first successful demonstration of the synthesis of an amino acid in the laboratory.

The overall reaction sequence shown below is now generally referred to as the Strecker synthesis:

where in $\text{R}_1\text{C}(\text{O})\text{R}_2$, R_1 and R_2 may be either a proton (H) or various substituted or non-substituted alkyl chains. Thus, both aldehydes and ketones can be starting materials for the Strecker synthesis, and depending on the nature of the aldehyde or ketone, amino acid products with different R_1 and R_2 substitutions can be generated.

This is generally accepted to be one of the principle mechanisms by which amino acids are synthesized in prebiotic simulations such as Miller-Urey synthesis and is likely one of the pathways for amino acid formation in ► [carbonaceous chondrites](#).

Definition

The Strelley Pool Formation (SPF) is a 3426–3350 Ma sedimentary succession that occurs in 14 greenstone belts in the East Pilbara Terrane (EPT) of the Pilbara Craton in Pilbara, Western Australia. The SPF is underlain and overlain unconformably by the dominantly volcanic Warrawoona and Kelly Groups, respectively. Its name is derived from a small pool known as the Strelley Pool occurring in the Pilgangoora Syncline. Its depositional area is assumed to cover more than 30,000 km², and the depositional environment ranges from shallow submarine to terrestrial. The SPF is known to contain morphologically diverse stromatolites and microfossils whose biogenicity has been extensively examined.

History

Identification of the sedimentary unit now assigned to the Strelley Pool Formation (SPF) dates back to 1972, when the unit was correlated to the Towers Formation (a term no longer used) of the Warrawoona Group. The SPF was previously called the Strelley Pool Chert (SPC), which Lowe (1980) introduced for outcrops at Strelley Pool in the Pilgangoora Syncline, approximately 30 km west of North Pole Dome. The SPF was once considered as a basal member of the Kelly Group (Van Kranendonk et al. 2004), but later reinterpreted as an independent formation separating the two major volcanic units of the Pilbara Supergroup, the Warrawoona, and the Kelly groups (Hickman 2008). The SPF is now identified in 14 greenstone belts in the East Pilbara Terrane (EPT) (Hickman *in press*).

Overview

The SPF is composed predominantly of sedimentary rocks such as sandstones, conglomerates, volcanoclastics, carbonates, evaporites, and cherts. Its depositional age is constrained by the ages of the underlying felsic volcanics of the Warrawoona Group (3433–3427 Ma) and the overlying basalts of the Euro Basalt of the Kelly Group (3350–3315 Ma) (Hickman, 2008). The basal unconformable contact includes a subaerial erosional unconformity (Van Kranendonk et al. 2006). Its thickness can be up to 1000 m. Lithostratigraphic subdivisions of the SPF, which were first proposed by Lowe (1983), ascend in the following stratigraphic order:

- Member 1, basal quartzose sandstone.
- Member 2, cherty unit of laminated flat stromatolite, conical stromatolite, and silicified evaporate.
- Member 3, stratified unit of stromatolite, black chert, silicified evaporite, and evaporate solution layer.
- Member 4, coarse, intraformational conglomerate and breccia.
- Member 5, cap unit of volcanoclastic debris.

As reported by Hickman (2008), on the other hand, this formation has significant lithostratigraphic variation both on regional and local scales. The SPF mostly represents shallow-water to subaerial environments, including shallow-water marine, coastal, and estuarine and non-marine such as lacustrine, fluvial, and sabkha (Hickman 2008; Allwood et al. 2006). Macroscopic biosignatures known as stromatolites have been identified as early as the 1980s. The SPF is also known to contain cellularly preserved microfossils of various morphologies and other biosignatures. These biosignatures are the focus of this contribution.

Basic Methodology

Studies of the SPF have been built on detailed fieldwork, including, for example, geological mapping, measuring sections, close examination

of outcrops, and careful collection of rock specimens with precise GPS (Global Positioning System) constraints. Reconstruction of local lithostratigraphy is essential for understanding paleoenvironment in which rocks containing potential biosignatures were formed. Collected hand specimens have been subjected to various analyses. Polished sections of hand specimen provide us with additional and detailed sedimentological information that could not be identified from outcrops. Microscopic examination of conventional petrographic thin sections is indispensable to make preliminary assessment of biogenicity of the fossil-like microstructures. Best targets for further analyses can be chosen only based on detailed and careful examination of petrographic thin sections. Representative further analyses include mineral and material identification, measurement of crystallinity of organic matter, elemental mapping, measurement of isotopic composition, and examination of nanoscale structures of putative microfossils and bulk rock chemical compositions. For these purposes, e.g., Raman Spectroscopy, Secondary Ion Mass Spectrometry (SIMS), Nanoscale Secondary Ion Mass Spectrometry (NanoSIMS), Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM), and Inductively Coupled Plasma Mass Spectrometry (ICP-MS) are used.

Key Research Findings

Stromatolite

The first description of stromatolitic structures in the SPF was made by Lowe (1980), who reported finely laminated conical mounds in chert in the East Strelley greenstone belt, which were correlated to *Conophyton* common in the Proterozoic. An outcrop displaying extensive conical to pseudocolumnar stromatolitic structures composed of carbonate was later discovered by A.F. Trendall (the Trendall locality) (Fig. 1a) from the Panorama greenstone belt. Hofmann et al. (1999) emphasized that purely chemical processes were insufficient for explaining several features of the SPF carbonate-facies stromatolites such as (1) the combination of steeply conical forms modified by second-order corrugate lamination; (2) the coexistence of cones with branching pseudocolumns; and (3) the juxtaposition of uniform laminae in cones with uneven wispy, lenticular horizontal laminae in intercone areas. The authors also mentioned the morphological similarity of the SPF stromatolites to younger varieties such as *Jacutophyton* and *Thyssagetes* and suggested that microbial activity was involved in the formation of the SPF conical stromatolites.

Biogenicity of the SPF carbonate-facies stromatolites has been further confirmed by Allwood

Strelley Pool Formation, Fig. 1 (a) Stromatolite cones at the Trendall locality in the Panorama greenstone belt, (b) silicified stromatolite-preserving organic laminae at the Waterfall locality in the Goldsworthy greenstone belt

et al. (2006), who described seven morphological types and related them to the variation in sedimentary environments determined through detailed mapping that covered several kilometers of outcrops. This macroscale analyses were combined with mesoscale to microscopic investigations of laminae architecture to successfully demonstrate the biogenicity of the SPF stromatolite. Habitat for the stromatolites was marine with some contributions of hydrothermal fluids (Allwood et al. 2010). The stromatolite locally preserves organic matter, whose carbon isotopic values are consistent with biogenicity and could further place some constraints on metabolism (Flannery et al. 2018). It was suggested that the reported large fractionation of carbon isotopes ($\delta^{13}\text{C} = -29 \sim -45\%$) between organic matter and associated carbonate reflected fixation and/or remobilization of carbon mediated by, for example, the Calvin-Benson-Bassham (CBB) cycle combined with the Wood-Ljungdahl pathway. From the SPF in the Goldsworthy greenstone belt, Sugitani et al. (2015b) reported siliceous stromatolites, in which carbonaceous laminae, trapped grains, and casts of possible evaporitic minerals are preserved. This newly described stromatolite varies in morphology from flat to columnar (Fig. 1b).

Carbon-isotopic compositions of carbonaceous laminae determined by SIMS are around 27‰. Habitat for these stromatolites was assumed to be nonmarine, based on rare-earth elements and yttrium systematics.

Cellularly Preserved Microfossils and Possible Microfossils

Fossil-like microstructures have been reported in several localities of the SPF. Schopf and Packer (1987) first described carbonaceous spheroids $\sim 20\ \mu\text{m}$ across and interpreted them as ensheathed colonial unicells. Sugitani et al. (2010, 2013, 2015a, b) and Schopf et al. (2017) reported morphologically diverse but basically identical assemblage of carbonaceous microstructures from the Panorama, Warralong, and Goldsworthy greenstone belts. The carbonaceous microstructures include spheroids, films, lenses, and filaments (Figs. 2 and 3): As such, the assemblage is basically similar to those reported from the contemporaneous ($\sim 3416\text{--}3330\ \text{Ma}$) Kromberg Formation in the Barberton greenstone belt, South Africa (Walsh 1992; Oehler et al. 2017) and from the ca. 3.0 Ga Farrel Quartzite in the Pilbara Craton (e.g., Sugitani et al. 2007). The SPF spheroid microstructures can be divided

Strelley Pool Formation, Fig. 2 (a) Colony of large spheroids with foam-like envelop; (b) loose cluster of gently sinuous cylindrical and hollow filaments

into two diameter categories, including small ($<15\ \mu\text{m}$) and large ($>15\ \mu\text{m}$), both of which occasionally occur as colony-like clusters (Fig. 2a). Some of filament-like structures are also clustered and comprise biomat-like fabrics (Fig. 2b) (Schopf et al. 2017). Lenses are composed of central spheroid body and surrounding discoid flange (Fig. 3a), ranging mostly from 40 to 80 μm along the major dimension.

Biogenicity of the SPF microstructures discovered by Sugitani et al. (2010, 2013) was assessed based on several criteria such as carbonaceous composition, size distribution, taphonomic features, and supposed physical property. The preliminary claims for biogenicity were supported by several followed-up studies. Lepot et al. (2013) performed SIMS analyses on small spheroids and lenses and revealed that these two morphological types had significantly light and distinct $\delta^{13}\text{C}$ values. Sugitani et al. (2015a) also successfully extracted lenses from host rocks by conventional acid maceration (Fig. 3b), demonstrating that they were composed of continuous membranous carbonaceous matter. TEM analyses of the extracted specimens showed that the central body of lenses

had inner alveolar structures which were likely originated from cytological complexity. Alleen et al. (2018) detected nitrogen- and oxygen-rich organic molecules from film and lens exposed on freshly fractured surface of the SPF chert. X-ray adsorption near edge structure (XANES) spectra of these microstructures was similar to those of the best-preserved microfossils in the 1.9 Ga Gunflint cherts. NanoSIMS analyses also demonstrated high N concentrations and substantial presence of P for spheroids, films, and spheroids (Delarue et al. 2020). Sugitani et al. (2018) performed morphometrics of extracted lenses (total analyzed number > 800) from two remote localities in the Goldsworthy and Panorama greenstone belts. Cluster analyses using three parameters of the whole area, the flange ratio, and sphericity revealed that each population was composed of three subpopulations and that the Panorama population is dominated by elliptic specimens, whereas the Goldsworthy population by circular ones. Trace element geochemistry of host rocks and lithostratigraphy suggest that the two habitats were environmentally different, namely marine (the Panorama locality) and nonmarine (the

Strelley Pool Formation, Fig. 3 (a) Two lenticular microfossils. The white arrow indicates an equatorial view, whereas the solid arrow does an inclined polar

view; (b) a slightly inclined polar view of specimen extracted from host rock by acid maceration

Goldsworthy locality), although both were influenced by hydrothermal activities. This morphological variation may therefore be a result of adaptive and geographical diversification. Another implication of this study is that SPF lenticular microbes have a common ancestor. One possible candidate is lenticular structures described from the Dresser Formation, although these were interpreted as volcanic vesicles by the discoverer (Wacey et al. 2018a).

Another assemblage of microfossils was reported by Wacey et al. (2011a), who described three morphotypes of putative microfossils from the basal sandstone of the SPF in the East Strelley greenstone belt, including small coccoids (~10 μm in diameter), sheath-like tubes (~10 μm in diameter), and large envelope-like spheroids (~80 μm in diameter). The authors performed focused ion beam system (FIB)-TEM and SIMS analyses of these structures and suggested that the specimens were fossils of sulfur metabolizing bacteria inhabited in an Archean sandy coastal environment. Wacey et al. (2018b), however, reinterpreted the clustered large spheroids as probable volcanogenic in origin (volcanic vesicles) and in extension implied the possibility that some of the lenticular microfossils described above (e.g., Sugitani et al. 2010, 2013) were volcanic vesicles colonized by microbes (biofilm).

Pyrite and Kerogen

In addition to the above-described cellularly preserved microfossils, possible noncellular biosignatures have been reported also from the basal sandstone of the SPF. The biosignatures include (1) pristine micron-sized pyrite with a $\delta^{34}\text{S}$ spread of $-12 \sim +6\text{‰}$ and $\Delta^{33}\text{S}$ (deviation from $\delta^{34}\text{S}$ – $\delta^{33}\text{S}$ correlation) with both positive and negative values of $-1.65 \sim +1.43\text{‰}$ and (2) detrital pyrite grains with minute spherical pits and chains of pits. The former is associated with organic material coating the framework quartz grains and is interpreted to provide evidence for microbial sulfate reduction and microbial disproportionation of elemental sulfur, whereas the latter is likely the result of microbially mediated oxidation of pyrite (Wacey et al. 2010, 2011b). Prior to these works, Marshall et al.

(2007) analyzed kerogenous materials extracted from the SPF and examined them using several spectrometric methods, including Fourier-transform infrared spectroscopy (FTIR) and catalytic hydropyrolysis followed by gas chromatography mass spectrometry (HyPy–GC–MS). The authors reported similarities of molecular profiles of HyPy products between SPF kerogens and unequivocally biogenic kerogens from the Mesoproterozoic Roper Group (~1450 Ma), and they implied that the SPF kerogens were biogenic.

Future Directions

Although a few skepticisms still remain (e.g., Wacey et al. 2018a, b), it now seems evident that the SPF contains well-demonstrated and various types of Paleoarchean biosignatures, including stromatolites, cellularly preserved microfossils, molecular fossils, and isotopic data of carbon and sulfur. Although some ideas have been proposed (e.g., Kozawa et al. 2019; Flannery et al. 2018), lifestyles, metabolisms, and biological affinities of stromatolite-builders and cellularly preserved microfossils are still poorly known. For example, despite its upward-growing morphology, phototaxis of microbes that had constructed stromatolite has not yet been fully confirmed (e.g., Bosak et al. 2009). This issue could be addressed by further detailed organochemical studies on early silicified stromatolites such as those discovered from the Goldsworthy greenstone belt (Sugitani et al. 2015b) in which organic laminae are well preserved: Exploring microfossils in them is challenging but intriguing. Additionally, systematic paleontology of cellularly preserved microfossils, which is indispensable for the assessment of Paleoarchean microbial diversity, should be established. As it is probable that lenticular microfossils can be discovered from older successions, search for them and demonstrating their biogenicity can also be expected. Finally, biological affinity (eukaryotic vs. prokaryotic and/or oxygenic photosynthesis vs. nonoxygenic photosynthesis) of lenticular microfossils should be one of the most important future research targets, although this

difficult task may need to be addressed with the development of new methodologies.

Laminated sedimentary structures · Microbial mats

Synonyms

Fossilized microbial mats; Living stromatolites; Microbialites; Modern stromatolites

Definition

Stromatolites are morphologically circumscribed accretionary growth structures with a primary lamination that is, or may be, biogenic. They form centimeter- to decimeter-scale domes, cones, columns, and planiform surfaces made of carbonate layers. Stromatolites accrete through a combination of microbially mediated sediment trapping and binding and by the precipitation of carbonate crusts that may be due to microbial mat growth and/or be purely ► [abiotic](#) in origin. Stromatolites provide the oldest macrofossil evidence of ► [life](#) on earth and sometimes host important ► [microfossil](#) occurrences. Images of macroscopically layered stromatolites obtained by rovers on other planetary surfaces may yet provide some of the first evidences of life beyond earth.

History

The term “stromatolith” was first used just over a century ago by Kalkowsky (1908) and derived from the Greek words *stroma* meaning bed, mattress, or layer, and *lithos* meaning stone. It was used to describe laminated limestones from the early Triassic, lacustrine deposits near the Harz Mountains of Northern Germany. Kalkowsky

attributed the formation of these structures to simple plant-like organisms, and the term was later popularized by Pia (1927) as a type of fossil produced by the calcium carbonate precipitation. The term was translated by Krumbein (1983) who stated that “stromatolites are organogenic, laminated, calcareous rock structures, the origin of which is clearly related to microscopic life, which in itself must not be fossilised.” It is now known that ► [prokaryotes](#) both photosynthetic and non-photosynthetic are largely responsible for stromatolite growth (Freytet and Verrecchia 1998), along with ► [heterotrophs](#), algae, and metazoans.

Overview

Stromatolites are the most abundant macrofossil in the ► [Precambrian](#) rock record and are volumetrically very significant components of Precambrian carbonate platforms. Stromatolites can be used to reconstruct sedimentary environments, especially paleobathymetry, paleoslopes, and current directions, and are used for biostratigraphic correlation within basins. Distinguishing the relative contribution of biological, physical, and chemical controls on stromatolite morphology can be difficult, and below the criteria that have been developed to assess the ► [biogenicity](#) of stromatolites are reviewed. The macro-morphology and especially microfabrics of stromatolites are archives of microbial evolution that together with their carbonate geochemistry record secular changes in seawater chemistry. This review focuses on how stromatolites grow and what they can tell us about the earliest microbial ecosystems on earth and perhaps beyond.

Basic Methodology

To study the microbial microtextures and carbonate mineralogy of stromatolites, light microscopy is widely applied. To investigate organic remains and the mineralogy, Laser Raman spectroscopy can be useful. If the samples are well-preserved with possible microbial remains, high-magnification microscopy techniques such as

scanning, and transmission electron microscopy, can be applied to rock samples and/or resin-impregnated nonlithified microbial mat remains. Geochemical information can be obtained on elemental abundances (major and trace), also isotopic ratios (see ► [Isotope Biosignatures](#)) using mass-spectrometry techniques, which may give bulk data from powdered samples, or in situ micro- to nanoscale data, if the mass spectrometer is coupled to a laser (laser ablation technique), or by using secondary ion mass spectrometry (SIMS).

Key Research Findings

What Is a Stromatolite?

The definition and meaning of the term stromatolite has been widely debated, especially whether the term should be used in a purely descriptive sense, to refer to laminated sedimentary structures, or should be used genetically to refer to structures that are demonstrably biogenic in origin; see reviews by, for example, Riding (1999), and Grotzinger and Knoll (1999). But herein lies the problem. There are many types of related geological structures that display some or all of the features of stromatolites, and are formed in a variety of environments, but with varying and sometimes debatable degrees of biological involvement. Such structures include hot spring travertines, nonmarine tufas, laminar caliche crusts, and speleothems. The possibility that abiotic processes may solely account for stromatolite growth was reasserted by Grotzinger and Rothman (1996) who used the Kardar-Parisi-Zhang (KPZ) equation of interface growth to show that the morphologies of some stromatolites can be modeled by abiotic processes alone. This was a significant study that reinvigorated the debate surrounding the biogenicity of Precambrian stromatolites in particular, and reemphasized the difficulties of disentangling biological, physical, and chemical controls on stromatolite growth. This remains a serious concern if we are 1 day to assess the biogenicity of laminated deposits imaged by rovers exploring other planetary surfaces.

A purely descriptive definition of a stromatolite was proposed by Semikhatov et al. (1979) and others: “an attached, laminated, lithified sedimentary growth structure, accretionary away from a point or limited surface of initiation.” Many sedimentologists favor this nongenetic definition to describe a laminated sedimentary structure with positive relief. This has resulted in the usage of terminology such as “abiogenic stromatolite” to stress the absence of compelling microtextural or morphological evidence for biological participation that is often lacking in many instances due to diagenetic alteration. Strictly speaking, however, this is a corruption of the original intention. The term stromatoloid has also been introduced by Buick et al. (1981) to refer to laminated sedimentary structures, the biogenicity of which is uncertain. An alternative approach to express the uncertainty surrounding the biogenicity of a given stromatolite is to add the prefix “probable” or “possible” or “dubio” stromatolite, as appropriate – this approach is applied to other biosignatures such as microfossils. Genetic definitions, on the other hand, have been proposed by, for example, Awramik and Margulis (1974), to mean an “organosedimentary structure produced by sediment trapping, binding, and/or precipitation as a result of the growth and metabolic activity of microorganisms, principally cyanophytes.” The evidence necessary to substantiate such a biogenic definition can be difficult to obtain in the rock record, especially in Precambrian sequences that have experienced diagenetic and metamorphic recrystallization – in this review, the term stromatolite is therefore used in the nongenetic sense.

Some workers, meanwhile, prefer the broader term *microbialite* that was introduced by Burne and Moore (1987) to describe both laminated and nonlaminated microbially mediated sedimentary structures. They defined microbialites as “organosedimentary deposits that have accreted as a result of benthic microbial community trapping and binding sediment and-or forming the locus of mineral precipitation.” Stromatolites are thus a subset of microbialites that also include nonlaminated deposits such as thrombolites (clotted) and dendrolites (branched) (Riding

1999). This term is perhaps most useful for describing modern microbial deposits that often exhibit varied internal structure and can be composite, including stromatolitic and other microbialite microfabrics. To add further confusion, the term stromatolite has also been applied to laminated microbial deposits that are not composed of carbonate, for example, laminated silica glazes or desert varnish crusts. Here, we will restrict our usage of the term stromatolite to carbonates.

Lithification of Recent Microbial Mats

Studies of modern stromatolite analogues both in nature and the laboratory have been very informative for understanding mechanisms of stromatolite growth and lithification. Many modern stromatolites are known from hypersaline settings, for instance, Shark Bay in Western Australia (Fig. 1a, b), where the hypersalinity is thought to restrict grazing on the mats. Here the stromatolites accrete at an estimated rate of ≤ 3 mm per year with microbial trapping and binding of sediment being the predominant accretion mechanisms in the intertidal stromatolites and carbonate precipitation in the subtidal stromatolites (Reid et al. 2003). Several modern stromatolite-forming microbial mat systems are also known from Lake systems such as Lake Pavilion in British Columbia and Lake Thetis in Western Australia, where elevated carbonate saturation levels are thought to promote lithification of the microbial mats. The only known modern open-marine stromatolite system comes from the Bahamas where stromatolites occur in supra-, inter-, and subtidal settings (e.g., Reid et al. 2000). Studies have found that the microbial mats are spatially and temporally very dynamic systems, with the location of primary production and lithification changing on diurnal to seasonal and annual cycles and across depositional gradients (e.g., Reid et al. 2003; Visscher et al. 2000). The distinct microenvironments, steep geochemical gradients, and diverse processes that occur within modern microbial mats are described elsewhere in this volume. Modern systems are, however, imperfect analogues for the Precambrian rock record, especially prior to the evolution of eukaryotes and

metazoans, and in a water column that was anoxic for much of the Archaean and early Proterozoic. Nonetheless, the manipulation of model microbial mat systems both in the lab and in their natural environment has proved informative for better understanding the mechanisms that produce specific stromatolite features, for example, cell motility in reticulate mats and oxygenic [photosynthesis](#) in conical mats (see below).

Stromatolite Biogenicity Criteria

The rock record provides a testing ground for developing stromatolite biogenicity criteria that 1 day may be applied to laminated sedimentary structures on other planetary surfaces. The problem is that most of these criteria are so prescriptive that the majority of Precambrian stromatolites of widely regarded biogenic origin fail to qualify. Here, a brief review of the most widely applied stromatolite biogenicity criteria is given, drawing from the classic study of Buick et al. (1981) and additional criteria (points 9–11) proposed by Hofmann (2000):

1. “*The structures must occur in undoubted sedimentary or metasedimentary rocks.*” A viable sedimentary environment is a necessary first condition to demonstrate the biogenicity of a stromatolite.
2. “*It must be demonstrated that the structures are syndimentary.*” It is necessary to exclude soft sediment deformation and/or later structural deformation as contributing to the resulting stromatolite morphology.
3. “*There should be a preponderance of convex upwards structures.*” This is a useful but very qualitative criterion and is neither necessary nor sufficient to demonstrate biogenicity as, for example, abiotic self-organizing structures such as stalagmites and agate crusts can exhibit convex-upward morphologies.
4. “*Laminae should thicken over the crests of flexures.*” This qualitative criterion is designed to exclude abiotic, chemical crusts that are widely believed to exhibit laterally uniform thickness, i.e., be isopachous (e.g., Pope and Grotzinger 2000). However, freshwater *Phormidium* stromatolites, for

Stromatolites, Fig. 1 Examples of stromatolites: (a) submerged intertidal modern stromatolites from Shark Bay, Western Australia; (b) living domal stromatolites with an orange diatom-rich coating from the intertidal zone of Carbla Foreshore, W Australia; (c) large columnar

stromatolite with smooth, convex laminae from the Neoproterozoic lower Transvaal Supergroup of South Africa; (d) microdigitate stromatolites from 2.7 Ga Tumbiana Formation of W Australia; (e) pseudocolumnar stromatolites from the Trendall locality of the ~3.4 Ga Strelley Pool Chert of

example, are commonly isopachous and can be differentiated from abiological speleothem cements by being of uniform thickness around, for example, the entire circumference of coated tree branches, whereas abiological cement would be thicker on the undersides due to geopetal effects. In other words, crusts do not need to thicken – they may just maintain their thickness. Further discussion on the different types of stromatolite laminar geometries is given below, including the degree of vertical inheritance between laminae and their lateral continuity.

5. *“If the structures are laminated the laminations should be wavy, wrinkled and/or have several orders of curvature.”* Again, this qualitative criterion is designed to exclude abiogenic precipitated crusts that are thought to be more uniform, but no limits are placed on the extent of “crinkliness” or “curvature” which are also controlled by sedimentary rheology and overprinted by the degree of diagenetic modification.
6. *“Microfossils or trace fossils should be present within the structures.”* This is far too rigid as the preservation potential of microbial remains is extremely low, such that this criterion would exclude more than an estimated 90% of described fossil stromatolites. Also, the majority of recent stromatolites only contain microorganisms in their outermost layers. Furthermore, the presence of microfossils in a stromatolite does not confirm their active role in formation of the structure, as they may simply have been passively entombed by the accreting structure, as is seen, for example, in some silica sinter deposits.
7. *“Changes in composition of the microfossil assemblages should be accompanied by morphological changes in the stromatolite.”* This is an extension of criterion 6 and is extremely prescriptive as only a few instances are known where this criterion is satisfied, for example, stromatolites of the Gunflint Chert. Studies of modern stromatolites also suggest similar fabrics can be produced by more than one organism, such that morphological changes may not necessarily accompany changes in microfossil assemblage.
8. *“The fossils or trace fossils must be organised in a manner indicating trapping, binding or precipitation of sediment by the living microorganisms.”* Again, this would be desirable but is somewhat overoptimistic in many settings. Likewise, tufted microbial filaments, fenestrae, and/or micropores created by the growth and decay of now absent microbes would be useful but are only found when diagenesis is minimal (e.g., Turner et al. 2000a).
9. *“Brecciated mat chips accumulated in depressions between convexly laminated mounds.”* These are occasionally seen and have been highlighted in discussions surrounding early Archaean stromatolites, for example, from the Strelley Pool Chert (Hofmann et al. 1999). Such textures are most convincing if the mat fragments show laminated internal fabrics or microtextures that can distinguish them from fragments of brecciated seafloor crusts.
10. *“Thin, rolled-up fragments as indications of the existence of coherent flexible laminae that are reasonably interpreted as microbial mats.”* These are desirable and occasionally seen, for example, in the Paleoproterozoic Hamersley Group of Western Australia and in silicified microbial mat horizons, for example, the 3.4 Ga Buck Reef Chert of South Africa (Tice and Lowe 2004), but again require exceptional organic preservation.
11. *“Distinct compositional differences between the laminated growth structures and their surrounding matrix, such as carbonate*

Stromatolites, Fig. 1 (continued) W Australia; (f) plan view of simple coniform stromatolites on a bedding surface of silicified carbonate from the W Strelley locality of the Strelley Pool Chert; and (g) domal stromatolite in a

ferruginous carbonate with a silicified core from the ~3.5 Ga Dresser Formation of the North Pole Dome, W Australia. Scale bar (a) and (b) 15 cm, (c) 20 cm, (d) 1 cm, (e) and (g) 5 cm, and (f) 10 cm

stromatolites set within terrigenous detritus.”

This can be a helpful criterion, but there are numerous exceptions. For instance, many of the least controversial carbonate stromatolites are found in carbonate settings, and especially those formed by trapping and binding can have a similar composition to their surrounding matrix. Whereas, in terrigenous clastic settings laminated carbonates are not always a stromatolite: Many caliche crusts would meet this criterion.

In summary, a biogenic origin is most likely for stromatolites that exhibit complex morphologies, laminae that show lateral and vertical variability (see discussion on microfabrics below), and organic bearing microfabrics. A more compelling case for a biogenic origin can be made, if it can also be shown that changes in both the macro- and microfeatures of the stromatolite correlate with biologically significant environmental gradients, such as light levels.

Mechanisms of Stromatolite Accretion

Here, the processes that contribute to stromatolite accretion are summarized, also the laminar geometries and microtextures that are thought to result. A schematic of these accretionary processes is shown in Fig. 2 (modified from Shapiro 2005); these are sediment trapping and binding (top left) producing often clotted or peloidal crusts, sometimes referred to as “fine-grained crusts”; chemical precipitation of carbonate (top right) producing laminae comprising “abiogenic sparry crusts”; a combination of these processes (lower left) producing composite crusts; and a skeletal stromatolite (lower right) formed by calcifying microorganisms, most commonly ► [cyano-bacteria](#). A more detailed review of this subject can be found in Riding (2008) that focuses on the microfabrics of Precambrian stromatolites.

Sediment Trapping and Binding

In recent stromatolites, the trapping and binding of suspended sediment particles is an important

Stromatolites, Fig. 2 Mechanisms of Stromatolite Accretion: (*top left*) sediment trapping and binding by microbial mats producing laminae with micritic, detrital, and/or peloidal layers; (*top right*) chemical precipitation of carbonate-producing laminae comprising “sparry crusts”;

(*lower left*) a combination of these processes producing composite crusts of alternating sparry, detrital, and organic layers; and (*lower right*) a skeletal stromatolite formed by calcifying microorganisms, for example, the cyanobacteria *Girvanella*. (Diagram modified from Shapiro (2005))

accretionary mechanism. This process is controlled by the slope of the accreting stromatolite interface, the grain size and density of the sediment particles, and the size and motility of the microbes (e.g., Riding (2000) and references therein). This process is countered by the movement of sediment down stromatolite flanks under the forces of gravity and current action that are most vigorous in high-energy settings and for stromatolites with steep flanks or significant relief. Sediment trapping and binding is thought to be facilitated by biofilms that have abundant “sticky” extracellular polymer and by microbes with high motility (e.g., Golubic et al. 2000). In addition, early cementation is necessary to prevent loss of this detrital sediment off the stromatolite flanks. These processes are thought to create nonisopachous laminae that show irregular uneven layering with low inheritance and limited lateral continuity. In petrographic thin section, preservation permitting the trapped and bound sediment grains should be visible, perhaps between the decayed remains of organic laminae that may have formed during more quiescent periods.

Trapping and binding processes are commonly associated with microbially induced carbonate precipitation (see below) that together result in so-called fine-grained crusts of Riding (2008). These can exhibit micritic, clotted, peloidal, or filamentous microfabrics and are especially abundant in the Neoproterozoic (e.g., Turner et al. 2000b). Additional support for microbial activity can come from microfossil remains, for example, in the 1.8 Ga stromatolites of the Gunflint (Awramik and Semikhatov 1978); or in the form of micropores interpreted to be the molds of decayed microbes (Bosak et al. 2004); or palimpsest fabrics comprising vertically aligned, decayed microbial filaments (e.g., Buick 1992). The mere presence of such microbial remains is insufficient, however, to demonstrate full microbial control on precipitation, as it needs to be shown that these remains were not just passively entombed but rather actively shaped by the accreting structure. In some stromatolites, the fine-grained crusts are interleaved with so-called crystalline or sparry crusts (see below) creating

alternating light and dark layers conferring a streaky appearance. These are interpreted to reflect the switching between dark, fine-grained essentially microbial-mediated layers and light-colored, possibly abiotically precipitated, spar layers that are common in many conical stromatolites termed *Conophyton* (e.g., Grotzinger and Knoll (1999), and references therein).

Abiotic Chemical Precipitation

Carbonate precipitation in microbial stromatolites not only can be induced by the activities of living and decaying microbes (e.g., Riding 2000), but also results from pore water supersaturation generated by abiotic processes such as degassing of CO₂ and evaporation. Abiotic chemical precipitation is responsible for the growth of abiotic laminated deposits, such as agates, botryoides, crystalline crusts, and cements. These can sometimes be recognized by the expansion and ultimate coalescing of neighboring crystal fans, or undulose layers with microfabrics clearly resulting from precipitation. These are termed “abiogenic sparry crusts” by Riding (2008). In discussions concerning the biogenicity of stromatolites, abiotic chemical precipitation is widely assumed to produce isopachous laminae, i.e., laminae of uniform thickness (e.g., Buick 1992). The synthetic stromatolite experiments reported in McLoughlin et al. (2008), however, together with several numerical modeling studies (e.g., Grotzinger and Rothman 1996), have shown that abiotic processes can also produce nonisopachous laminae, and therefore stromatolite imposters or pseudofossils. This is well known. For example, meteoritic cements formed in the phreatic zone, where void spaces are water filled, result in the precipitation of cements with isopachous laminae, whereas cements formed in the vadose zone have dripstone, i.e., nonisopachous geometries. Thus, the assumption that abiotic precipitation exclusively results in isopachous stromatolite laminae does not hold. This raises further concerns about our abilities to always identify abiotic laminated deposits confidently.

In the Precambrian rock record, stromatolitic growth by abiotic, surface-normal chemical precipitation is suggested by laminae that are

composed of radial fibrous crystals fans (Fig. 2c) (e.g., Grotzinger and Knoll 1999) or so-called sparry crusts (Riding 2008). These are characterized by isopachous laminae that show extreme lateral continuity and high degrees of vertical inheritance. Such structures are believed to form by direct carbonate precipitation on the seafloor and are devoid of clastic carbonate (e.g., Turner et al. 2000b; Pope and Grotzinger 2000). They are particularly abundant in Archaean and Paleoproterozoic sequences and are believed to be associated with times of high seawater carbonate supersaturation, often being associated with evaporitic sequences. They have been termed “chemical stromatolites” by Pope and Grotzinger (2000) who argued that they are largely abiotic in origin.

Biologically Induced Precipitation: Chemo- and Phototaxis

The thickening of laminae across the crests of stromatolite domes and cones is commonly believed to result from microbially accelerated growth in an upward direction due to chemo- or phototaxis. Coniform stromatolites are taken as indicators of phototactic microbial growth by analogy to modern-tufted and peak-shaped microbial mats (e.g., Walter et al. 1976; Batchelor et al. 2004). It is envisaged that phototactic biofilms strive to gain more light and that chemotactic biofilms aim to elevate themselves in the benthic boundary layer to access more nutrients. This accelerated upward growth is accomplished by microbial motility toward topographic highs termed “upslope diffusion” by Jogi and Runnegar (2005). The exact geometries of the resulting laminae, in particular, the degree of laminar thickening in the axial zone, are likely controlled by photic zone conditions, the thickness of the benthic boundary layer, and the nature of diffusive gradient both within and above the accreting surface. Recent laboratory investigations of reticulate cyanobacterial mats have found that it is cell motility and not phototaxis that controls the shape of the mat, because upward growth was observed even when illuminated from below (Shepard and Sumner 2010).

In addition to laminar geometries, there are other microfabric clues that may indicate the

phototactic growth of stromatolites. Recent laboratory experiments growing cyanobacterial-dominated microbial mats have identified the presence of contorted laminae in the axial zone of conical aggregates and preservation of enmeshed oxygen bubbles as indicators of oxygenic photosynthetic mat growth (Bosak et al. 2009). Such features are found in the central zones of well-preserved Proterozoic conical stromatolites from which these workers argue that oxygenic photosynthesis first appeared in the Paleoproterozoic. In outcrop, the observation of sinuous growth axes of 850 Ma stromatolites from the Bitter Springs Formation has also been argued to represent heliotropism, i.e., microbial mat growth that tracks the changing position of the sun (Vanyo and Awramik 1985) – this of course requires that the stromatolites were accreting and lithified at a sufficiently fast rate to record such annual variation.

Brief Review of Stromatolites Through Time

There have been many attempts to compute curves of stromatolite diversity and abundance through geological time; however, these efforts have been somewhat hampered by our inability to separate biological, chemical, and physical controls on stromatolite growth and to agree a universal definition of what constitutes a stromatolite taxon (Grotzinger and Knoll 1999). There are, nonetheless, long-term, first-order trends in stromatolite morphologies and microfabrics that record evolutionary and environmental changes that are summarized here.

First, there is a broad transition in the Precambrian from stromatolites formed predominantly by chemical precipitation in the Archaean with sparry microfabrics to stromatolites with fine-grained more microbially influenced microfabrics in the Neoproterozoic (Riding 2008). In the intervening Paleo and Meso-proterozoic interval, stromatolites with hybrid fabrics are most common, and this is argued to reflect growth by a combination of chemical precipitation and sediment trapping and binding. This transition has been suggested to represent a long-term decline in Precambrian seawater carbonate supersaturation (Grotzinger and Kasting 1993), with a consequent

switch in importance from chemical precipitation to microbial trapping and binding as the dominant mechanisms of stromatolite growth. This connection between seawater carbonate saturation and microbialite abundance has been further tested in the Phanerozoic with compilations of abundance data for calcified cyanobacteria and microbial carbonates (Riding and Liang 2005 and references therein) showing a positive correlation with marine carbonate saturation.

Second, distinctive new stromatolite morphologies and/or microfabrics can record major evolutionary events. For example, cyanobacterial biomineralization in the lower Cambrian (Riding and Voronova 1984) resulted in the formation of dendrolites and skeletal stromatolites, which are most abundant in the Cambrian and Lower Ordovician. Also thrombolites, with their clotted microfabrics, first appear in the Cambrian, and they are argued to represent “disturbed stromatolites,” in which the activities of animals and ► [algae](#) have disrupted and destroyed the laminae (Walter and Heys 1985). In addition, the abundance of microbial carbonates in the Phanerozoic is generally inversed to that of marine metazoan taxonomic diversity, supporting the view that metazoan competition has progressively limited the formation of microbial carbonates. Further, stromatolite morphologies that may be diagnostic of certain periods of geological time have been recognized, although their environmental and/or evolutionary significance is yet to be fully understood. For instance, many late Archaean carbonate sequences include fenestrate microbialites, netlike masses of irregular columns, or tent shapes composed of dark organic layers encased in irregular calcite cements (Sumner 1997), but their apparently restricted time distribution is yet to be fully explained.

Third, stromatolites have been suggested as disaster taxa, namely, organisms that in the aftermaths of mass extinction events show increased abundance due to the relaxation of ecological constraints. For example, in Lower Triassic strata following the end-Permian mass extinction that was particularly devastating to benthic biota, a time dominated by depositional systems reminiscent of the Neoproterozoic-Early Paleozoic has

been reported. In particular, this includes planar microbialites, small stromatolites, thrombolites, and microbial reefs developed extensively in normal marine carbonate environments. The proliferation of these so-called disaster taxa has been attributed to a reduction in trace fossil infaunalization and metazoan grazers. But there may be other environmental factors at play, including the enhanced carbonate saturation at this time as supported by the abundance of seafloor crystal fans that would promote the lithification of benthic microbial mats. A more recent study from the Phanerozoic of North America (Peters et al. 2017) found that the aftermaths of major mass extinction events are not well correlated with stromatolite resurgence. Instead, stromatolite occurrence is well-predicted by the prevalence of dolomite, and a shift in carbonate mineralogy that is sensitive to changes in water-column and pore-water chemistry occurring during continent-scale marine transgressive-regressive cycles. These findings again highlight the difficulties of separating physical, chemical, and biological controls on stromatolite growth and abundance.

The Oldest Stromatolites on Earth

The oldest known stromatolites are described from silicified carbonates of the Pilbara Craton, Western Australia. Archaean ► [traces of life](#) are reviewed elsewhere in this volume, and here the focus is on the macrofossil evidence provided by stromatolites. A comprehensive summary of all reported Archaean stromatolite occurrences can be found in Table 1 of Hofmann (2000). The oldest candidate stromatolites come from the <3.49 Ga Dresser Formation of Western Australia and include wrinkled planiform surfaces, broad domes, and columnar forms (Fig. 1g). These occur at several localities in the North Pole Dome both in syn-depositional barite mounds and hydrothermal dykes and in silicified and hydrothermally altered ferruginous carbonates (Wacey 2009 and references therein). Early studies supported a biological explanation from these structures based on macromorphological similarities to younger, unambiguously biological stromatolites (Walter et al. 1980). However, Lowe

(1994) reinterpreted these structures as soft sediment deformation features, and Buick et al. (1981) concluded that they were only “*probable or possible*” biogenic stromatolites because they failed to satisfy many of their biogenicity criteria reviewed above. More recent studies have argued largely on the basis of field relationships that these stromatolites are primary features that were constructed by hyperthermophilic microbes (Van Kranendonk 2007). The depositional environment has also been variously interpreted as a seafloor hydrothermal “white smoker” type deposit, and more recently as a terrestrial hot-spring biogenic geyserite deposit (Djokic et al. 2017). A variety of other candidate microbial biosignatures have been described and debated from the North Pole locality, including microfossils, C-isotope and fluid inclusion evidence, microbially induced sedimentary structures, and S isotopes on sulfide minerals that are discussed in a separate entry: ► [Dresser Formation, Traces of Life](#).

Some of the next oldest putative stromatolites are described from the <3.4 Ga Strelley Pool Chert of Western Australia; the most abundant forms are simple unbranched cones (Fig. 1f) that were initially interpreted as biogenic in origin, but this interpretation was later rescinded in favor of an origin by abiogenic evaporitic precipitation (Lowe 1994). The discovery of large coniform stromatolites with rare flank structures and domal and laterally linked pseudocolumnar morphologies (Fig. 1e) at the Trendall locality in the North Pole Dome led to a biological origin for these structures being readvanced (Hofmann et al. 1999). This was argued for based on morphological and sedimentological evidence, especially the steep-sided cones argued to require cohesive microbial mats, the presence of detrital sediment taken to imply microbial tapping and binding, the wrinkly nature of the laminae, and microfabric differences between the stromatolites and intervening nonstromatolitic sediments (Hofmann et al. 1999). Subsequently, detailed mapping of the stromatolite macromorphologies and investigation of rare outcrops with relatively good microtextural preservation have found evidence for a spatiotemporal correlation between

stromatolite morphology and microfabric and depositional environment. This has been taken to support a shallow-water carbonate platform depositional model for the Strelley Pool Chert and a phototrophic origin for the stromatolites (Allwood et al. 2009). Regionally, however, the more typical, small, unbranched coniform stromatolites of the Strelley Pool Chert do not show unambiguous biological characteristics or depth-controlled distribution and/or changes in morphology with depth (Wacey 2010). In addition, their close interrelationship with crystal fan arrays upon which they can be seen to nucleate emphasizes a strong chemical component to their growth, and their intergradation with linguoid current ripples highlights the importance of physical controls on their accretion. In short, the Strelley Pool Chert includes a spectrum of stromatolitic structures, only some of which are confidently interpreted as biogenic.

Older still, convex-up structures initially interpreted as stromatolites were described from 3.7 Ga metasediments of the Isua Supracrustal Belt (Nutman et al. 2016). These structures occur in tightly folded rocks and comprise both convex-up structures adjacent to convex-down structures and, therefore, fail the requirements for syn-sedimentary structures, with a predominance of convex-up morphologies, and so were reinterpreted as deformation features (Allwood et al. 2018). In addition, the depositional setting of these rocks has been questioned, with major and trace element geochemistry suggesting that the carbonate is more likely secondary (metasomatic/metamorphic) in origin and not primary seafloor deposits (Allwood et al. 2018).

Applications

In the near future, images of layered extraterrestrial sediments will be collected by rovers or landers on other planetary surfaces, most immediately Mars. We therefore require tools for assessing if these deposits were microbially shaped and/or if their mineralogy reflects microbial involvement. One approach involves quantitative image processing tools to measure the

degree of ► [complexity](#) in images of laminated deposits (Wagstaff and Corsetti [2010](#)) that may help select targets that are most likely biogenic, and perhaps promising for sample return missions. Currently, NASA's Mars Perseverance rover is deploying the PIXL (Planetary Instrument for X-ray Lithochemistry), which is a micro-focused X-ray fluorescence spectrometer mounted on a robotic arm (Allwood et al. [2020](#)). This instrument contains a powerful 120 μm -diameter X-ray beam with enough sensitivity to detect major and minor rock-forming elements, as well as many trace elements. This instrument can map the distribution and abundance variations of chemical elements making up a rock, tied to the physical texture and structure of the rock, which would be especially useful for assessing the origin of laminated deposits, particularly stromatolites. Other instruments that can be mounted on rovers and might be developed for future missions to investigate the carbonate mineralogy, and/or organic carbon content of stromatolites, include Raman spectrometers (Rividi et al. [2010](#)).

Future Directions

Stromatolites provide one of the most abundant and richest records of microbial evolution on our planet, but we are yet to fully decode the physical, chemical, and biological processes that are encoded in their diverse shapes and microfabrics. Promising approaches that are being developed include nanoscale elemental and isotopic signatures of organic matter found in well-preserved stromatolites (Lepot et al. [2009](#); Wacey et al. [2010](#)). Also, radiogenic and stable isotopes techniques are being revisited and further developed to directly date stromatolites and determine the source of elements in ancient stromatolite environments (radiogenic isotopes), and to understand redox conditions, metal availability, and (biogenic) metal cycling processes in microbial habitats (stable isotopes) as recently reviewed by Hohl and Viehmann ([2021](#)). Together with studies that manipulate living microbial mat systems to investigate the resulting morphological and chemical signatures produced in lithified stromatolites,

we are becoming better prepared to assess the biogenicity of stromatolites that may someday soon be found on other planetary surfaces.

Structure and Chemistry of Microfossils

► Microfossils, Analytical Techniques

Subduction

Nicholas Arndt

Emeritus Professor, ISTerre, University Grenoble Alpes, Grenoble, France

Definition

A basic tenet of ► [plate tectonics](#) is that ► [oceanic crust](#) forms at ► [mid-ocean ridges](#) and cycles back into the mantle, usually at the margins of ocean basins (called *convergent margins* because plates converges, one subducting beneath another). The latter process is called subduction, and the regions where it happens are called subduction zones. At mid-ocean ridges, seawater penetrates the basaltic crust and converts the upper portions of the crust to an assemblage of hydrous minerals; as temperature and pressure increase during subduction, these hydrous minerals are destabilized. The released aqueous fluid triggers melting in the mantle overlying the subduction zone (the so-called mantle wedge) to yield calc-alkaline magmas and explosive volcanism producing *volcanic arcs* above subduction zones. Subducting plates correspond also to an inclined zones of earthquakes – the so-called Wadati-Benioff zone from the name of the discoverers – at the contact between the subducting plate and the overlying mantle. Evidence of past subductions are rare for the other telluric planets of our Solar system. It has

been suggested that the Tharsis rise on Mars could have been triggered by subduction of Martian crust provoked by large asteroidal impacts (Yin 2012).

Subglacial Environments

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

Subglacial is a term defining environments in a glaciated area, which lie directly beneath an ice mass and in close contact with the overlying ice. These environments include cavities and channels beneath the ice that are not influenced by subaerial processes (i.e., processes that take place in open air or adjacent to the land surface). Subglacial lakes, such as Vostok Lake in Antarctica, are subglacial environments. In astrobiology, these

environments are studied to understand how life survives in extremely cold habitats and often under suboxic conditions. Subglacial lakes seem to be present beneath the Mars' Southern Pole and possibly exist on icy moons Europa and Enceladus.

Sublimation

Mark Dörr

University of Southern Denmark, Odense M, Denmark

Definition

Sublimation (Lat.: *sublimis* = “elevated,” “lofty”) is a special phase transition of an element or compound: the transition from a solid phase to a gas phase without intermediate liquid stage.

Sublimation is usually an ► [endothermic](#) phase transition that occurs at temperatures and pressures below the ► [triple point](#) of a substance. The opposite of *sublimation* is *deposition*. The formation of rime is an example of meteorological *deposition*, and its sudden disappearance at temperatures below the freezing point of ► [water](#) is an example of *sublimation*.

Definition

The Submillimeter Wave Astronomy Satellite (SWAS) was a ► [NASA](#) mission dedicated to the study of interstellar chemistry. SWAS was launched in 1998 December and acquired data until 2004 July. SWAS was reactivated in 2005 June for a 3-month period to provide support for the Deep Impact mission. SWAS was comprised of a 54×68 cm off-axis Cassegrain telescope feeding two independent passively cooled heterodyne receivers. SWAS observed simultaneously the transitions of four astrophysically important species: O_2 (487.2 GHz), neutral atomic carbon (492.2 GHz), ^{13}CO (550.9 GHz), and H_2O (556.9 GHz) and it could also be tuned to observe $H_2^{18}O$ (547.7 GHz). The spectra were recorded using an Acousto-Optical Spectrometer (AOS) which provided a total bandwidth of 1400 MHz for the four lines of primary interest. Observations of over 200 targets in more than 5000 lines of

sight were obtained over its lifetime and were used to study the chemistry of interstellar molecular clouds, circumstellar envelopes of evolved stars, planetary atmospheres, and comets.

Suboxic

Daniele L. Pinti
Geotop, Research centre for the dynamics of the
Earth system, Université du Québec à Montréal,
Montréal, QC, Canada

Synonyms

[Poorly oxygenated](#)

Definition

Suboxic is an adjective used for describing the oxygen concentration in the water column or any other environment (pore water, sediments, etc.) where oxygen is strongly limited and shows no perceptible vertical gradients. The boundary between hypoxic and suboxic conditions is widely taken as $10 \mu M$ of O_2 . This level probably corresponds to the biochemical threshold below which the dominant electron acceptors are oxidized species of N (nitrate, nitrite) or of metals [Mn(IV), Fe(III)], while dissolved oxygen becomes an auxiliary oxidant. Suboxic zones favor denitrification which in turn removes many essential nutrients from the water column. In astrobiology, suboxic environments are of interest because they could yield clues on the development of metabolic pathways in which oxidants were limited (e.g., nitrification/denitrification), possibly the case of stepwise oxygenating Proterozoic oceans.

Keywords

Oxygen · Redox · Diagenesis · Organic carbon · Microbes · Respiration · Pore waters

Definition

The suboxic zone lies between the oxic and anoxic zones, where the concentrations of both dissolved oxygen and sulfide are low. Sediment pore waters are generally driven to suboxic

conditions via microbial degradation of organic matter, and these intermediate waters commonly host the biogeochemical cycling of nitrogen, manganese, and iron. Suboxic pore waters modify the chemistry and mineralogy of sediments between their deposition and eventual burial and represent an important component of early diagenesis.

History

A classification scheme for suboxic sediments was originally outlined by Froelich et al. (1979), based on chemical profiles of pore waters within marine sediments. These sediments were deposited below oxygenated bottom waters, but contained sufficient organic carbon to consume oxygen (via aerobic respiration) from pore waters. Froelich et al. (1979) defined suboxic sediments as those which support the reduction of nitrate, manganese, and iron before the onset of sulfate reduction and methanogenesis (Fig. 1). A later classification scheme outlined by Berner (1981) proposed the term “post-oxic” as an alternative to suboxic, and this equivalent term is sometimes seen in the literature.

The term suboxic has since become popular among biogeochemists, but is often applied rather randomly, with different intended meanings. For example, the term suboxic is sometimes used to imply low, but significant, oxygen levels (e.g., 1–10 μM , Oakley et al. 2007). However, the concentration of O_2 at which nitrate, manganese, and iron reduction occur is variable, and this O_2 range risks incorporating the process of aerobic respiration of organic matter (Christensen et al. 1989). Furthermore, iron reduction has historically been included as a suboxic process despite occurring under strictly anaerobic conditions. As such, suboxic conditions cannot be defined based on oxygen levels alone.

Another source of confusion has been the application of the term suboxic to describe sediments. This can variably refer to sediments deposited beneath suboxic bottom waters or to suboxic pore waters within the sediment pile. It is important to distinguish between these two meanings, given that with a sufficient supply of organic matter, pore waters are commonly driven to suboxic and anoxic conditions even below well-oxygenated bottom

Suboxic Sediments, Fig. 1 Generalized scheme showing the energy yield (ΔG) for each respiration processes (left) and the associated sedimentary chemical zone (right). Relative concentrations of oxidized species, such as

oxygen (in blue), and reduced metabolic products, such as nitrite (orange), Mn^{2+} (pink), Fe^{2+} (green), sulfide (yellow), and methane (brown), are shown in cartoon form on the right. (Adapted from Froelich et al. 1979)

waters. This distinction may be clarified by using the terms “sediments deposited below suboxic waters” or “suboxic pore waters.”

While geochemists use the term suboxic to refer to specific biogeochemical processes, sedimentologists commonly apply the term to describe paleoenvironments on the basis of mineral assemblages in sedimentary rocks. For example, minerals such as glauconite can indicate that oxygen was present intermittently (Berner 1981).

To ameliorate this confusion, a new scheme was outlined by Canfield and Thamdrup (2009). They proposed that the nebulous term suboxic is, where possible, replaced with a description of the individual metabolic zone, identified by its chemical signature. However, the term suboxic has persisted in the literature and can be useful when collectively referring to the biogeochemical cycling of nitrate, manganese, and iron.

Overview

The microbial oxidation of organic carbon can be coupled to the reduction of oxygen or to a series of

alternative oxidized species with lower reduction potentials, each one liberating less energy than the last. In general, microbes do not begin to respire the next species in the hierarchy until the more desirable one has been significantly depleted. This is reflected in the sediments, where pore waters become stratified into distinct chemical zones with depth.

The first alternate metabolic zone is the nitrogenous zone, which hosts nitrate reduction (or denitrification). This involves the reduction of nitrate to nitrite, which is then converted to N_2 gas or ammonia. The nitrogenous zone can be detected by the associated nitrite peak in pore waters. The second alternate metabolic zone is the manganous zone, where $\text{Mn}(\text{IV})$ oxide minerals are reduced to aqueous Mn^{2+} . The onset of manganese reduction occurs below the nitrite peak, but commonly overlaps with the base of the nitrogenous zone. In sediments, the top of the manganous zone is often marked by a distinct layer of MnO_2 , as upward-diffusing Mn^{2+} encounters nitrate or O_2 . In practice, the manganous zone is often insignificant due to the low

abundance of Mn oxide minerals in most sedimentary systems (Calvert and Pedersen 1996).

Below the manganous zone is the ferruginous zone, where Fe(III) oxide minerals are reduced to ferrous iron, Fe^{2+} . Iron reduction proceeds first with highly reactive ferric hydroxides, but as these become depleted, microbes utilize more crystalline phases such as hematite, goethite, or magnetite. Some of the Fe^{2+} generated may diffuse upward and be re-oxidized via reactions with MnO_2 , NO_3^- , or O_2 . As such, Fe^{2+} only accumulates under fully anoxic conditions.

The term suboxic is used to collectively refer to the nitrogenous, manganous, and ferruginous zones. In practice, it is often easier to identify the metabolic zone by the impact it has on pore water chemistry, rather than by detecting the activity of the responsible microbes. As such, the zones are defined by the loss of reactants, such as nitrate, or the buildup of aqueous products, such as Mn^{2+} or Fe^{2+} . Where metabolic zones overlap, the zone should be assigned according to whichever metabolic product is most abundant (Canfield and Thamdrup 2009).

The dominant microbial metabolisms and their chemical fingerprints do not always perfectly overlap. Firstly, chemical products may persist in the absence of active metabolic production. For example, Mn^{2+} removal is governed by the precipitation of Mn carbonate minerals, such as kutnohorite and rhodochrosite, and thus Mn^{2+} -enriched pore waters may persist below the zone of active production and well into the anoxic zone. The manganous zone must therefore be defined by the accumulation of Mn^{2+} in the absence of other anaerobic metabolic products. Secondly, reactions other than anaerobic respiration may produce nitrite, Mn^{2+} , or Fe^{2+} as a by-product. For example, chemolithoautotrophic bacteria may drive manganese reduction coupled to the oxidation of iron sulfide minerals. While the chemical fingerprint may be similar, Mn^{2+} buildup under these conditions is differentiated by context.

In contrast, chemical products may not be detectable despite active metabolic production. For example, sulfide produced through sulfate reduction can be rapidly oxidized by iron oxide minerals, pushing the top of the sulfidic zone to

greater depths than the onset of active sulfate reduction (e.g., Canfield et al. 1992). In this case, active sulfate reduction may either be measured directly using radiolabeled $^{35}\text{S}\text{-SO}_4$ or indirectly indicated by the formation of iron sulfide minerals (e.g., pyrite, FeS_2). Thus these metabolic processes would often go undetected using traditional geochemical techniques, and yet they play an important role in energy fluxes and elemental cycling.

[Substratum](#)

Definition

In chemistry, a substrate is a substance that is acted upon by a ► [catalyst](#). The word substrate is a composite of the Latin terms *sub* “below” and *stratum* “layer.” In modern organisms, protein- or RNA-based polymers (enzymes and ribozymes, respectively) serve as catalysts that act upon various substrates, or reactants, which can be organic or inorganic. Substrates and catalysts are usually distinct entities, and depending on the reaction in question, a catalyst may react with two substrates together simultaneously or act promiscuously on various structurally related substrates.

In the case of a single substrate, the substrate binds with the enzyme or catalyst ► [active site](#), and a catalyst-substrate complex is formed. The substrate is then catalytically transformed into one or more products, which are then released from the active site.

where C is the catalyst (a surface, enzyme, ribozyme, or other species), S is the substrate (or substrates), and P is the product (or products).

In cases with more than one substrate, these may need to be bound in a particular order, before reacting together to produce products.

In the context of astrobiology, the clear discrimination between substrates and catalysts is difficult since complex catalysts such as enzymes and ribozymes were likely not present during the first stages of chemical evolution. Accordingly, the emergence of the first substrates and catalysts can be envisioned as their annealing from an initial network of diverse interactions between various small molecules.

Definition

Succinic acid ($\text{HOOCCH}_2\text{CH}_2\text{COOH}$) is a ► [dicarboxylic acid](#) which plays an important role in the ► [citric acid cycle](#). The name comes from Latin *succinum*, meaning amber, from which the acid was first isolated. The carboxylate anion is called succinate. Succinic acid has a melting point of 185 °C and a boiling point of 235 °C.

In the citric acid cycle, succinic acid donates electrons to FAD (flavin adenine dinucleotide) and ultimately to the electron transport chain by the reaction

This reaction is catalyzed by the enzyme succinate dehydrogenase.

Succinic acid has been produced in various prebiotic experiments and has been found in carbonaceous chondrite meteorites.

Sudbury · Impact structure · Canada

Definition

Sudbury crater is a large impact structure, originally about 200–250 km in diameter and 1.86 billion years old.

History

The almost two-billion-year-old Sudbury impact structure in Canada is one of the oldest known impact structures on Earth. Collisions and impact processes have been important throughout the history of the solar system, including that of the Earth. Small bodies in the early solar system, the planetesimals, grew through collisions, ultimately forming the planets. The Earth started growing about 4.56 billion years ago in this way. During the first several hundred million years, the Earth must have been subjected to an intense early impact flux, the (late) heavy bombardment period.

In terms of evidence for impact on Earth, the first solid evidence exists in the form of various impact-derived spherule layers found in South Africa and Australia with ages between about 3.4 and 2.5 Ga; these layers represent several (the exact number is still unknown) large-scale impact events. The oldest documented (and preserved) impact structures on Earth have ages of 2.23, 2.02 and 1.85 billion years. Thus, the impact record for more than half of the geological history of the Earth is incomplete and not well preserved, and we mostly have only indirect evidence regarding the impact record and its effects during the first 2.5 billion years of Earth history.

Overview

The currently visible structure is deeply eroded and highly deformed (Fig. 1). The term Sudbury

Structure collectively refers to the brecciated country rocks of the Superior and Southern provinces of the Canadian Shield in the environs of the Sudbury Igneous Complex, the SIC with its ore deposits, and the interior Sudbury Basin. Its origin has been debated for more than 100 years since its discovery in the late nineteenth century. An impact origin for Sudbury was first proposed in 1962, and confirmed by Dietz (1964) from the presence of shatter cones (see also Fig. 2). Later, microscopic planar deformation features (PDFs) were found in quartz in clasts of the Onaping Formation; such microstructures are unambiguous evidence of shock metamorphism and thus an origin by impact.

World-class Ni-Cu sulphide deposits, also containing noteworthy platinum group metal mineralization, are associated with the Sudbury Igneous Complex (SIC) in the central part of the Sudbury Structure (e.g., papers in Pye et al.

Sudbury Impact Structure, Fig. 1 The kidney-shaped Sudbury Basin, the eroded and highly deformed remnant of the Sudbury impact structure, is visible in the center of

the image, whereas on the upper right the (much younger) Lake Wanapitei impact structure can be seen (NASA Landsat image, Wikipedia, public domain)

Sudbury Impact Structure, Fig. 2 Shatter cones within the Sudbury impact structure; such features are uniquely characteristic of shock metamorphic processes and thus confirm an impact origin of the structure (image width ca. 50 cm; photo: C. Koeberl 2003)

1984; Naldrett 2003). The SIC is ca. 2.5 km thick and forms an elliptical body of about 27×60 km extent. The entire Sudbury Structure covers a much larger area, of some 15,000 km². This includes, besides the SIC, the fractured, brecciated, and shocked footwall rocks of the structure, namely the Archean basement to the north and east of the SIC, and the supracrustal rocks of the Proterozoic Huronian Supergroup south of the SIC, and the impact breccias, mudstones, and graywackes of the Whitewater Group in the Sudbury Basin, overlying the SIC (e.g., Dressler et al. 1991). The original diameter of the Sudbury impact structure, before deformation, has been estimated at around 200–250 km, making it the second largest currently known impact structure on Earth. For economic reasons, the SIC has been the focus of much of the past investigations in the Sudbury Structure (cf. Reimold et al. 2005). The Ni and other related mineralizations are of terrestrial

origin, and at least in the mineralized samples, no chemical or isotopic traces of the asteroid were found. Only from siderophile element (including platinum group elements, PGEs) analyses of samples from the Onaping Formation did Petrus et al. (2015) find evidence for an ordinary or enstatite chondrite as the most probable source of meteoritic material in the Sudbury crater fill.

Ejecta from the Sudbury impact were only recently discovered. A small number of studies have examined ejecta from the impact; for example, Addison et al. (2005) first described the ejecta and constrained the age of the deposits, and Cannon et al. (2010) examined a variety of known sites across Michigan, the USA, examining geochemistry and petrography, whereas Huber et al. (2014) found elevated abundances of PGEs from three sites and examined the detailed petrography of melts in the ejecta, confirming indications of evidence of a possible chondritic component in the ejecta. Chromium-isotope data on Sudbury ejecta record a complex meteoritic signature that could indicate the impact of a heterogeneous chondritic body (Mougel et al. 2017).

Meteorite impact-generated accretionary lapilli are not well studied. (Accretionary lapilli are millimeter- to centimeter-sized objects that are usually known from volcanic eruptions, where rounded pellets form by the accretion of ash or dust around moisture droplets, and they often show concentric rings; similar objects can also form in impact ejecta clouds.) The recently discovered distal ejecta from the 1850 Ma Sudbury impact event contain abundant accretionary lapilli generated during the impact and deposited at great distances from the crater. Huber and Koeberl (2017) petrographically and geochemically examined lapilli from five sites (McClure; Connors Creek; Hwy 588; Pine River; and Grand Trunk Pacific, ca. 480–750 km from the center of the Sudbury structure). In these studies, it was found that the compositions of quartz, K-feldspar, calcite, biotite, and chlorite minerals are similar to each other in all of the samples, although the relative proportions of the minerals vary from site to site. The lapilli occur in a matrix of coarse-grained quartz, carbonate, and feldspar grains. Zonation within lapilli appears to be due to grain size distribution rather than compositional

variation. The inner zones are coarser grained than outer zones. The relative abundances of calcite, phyllosilicates, and feldspars are similar in each zone within individual lapilli. The presence of a meteoritic component is indicated by up to 1.8 ppb Ir in one lapillus from the Pine River site; in addition, for many of the lapilli Ni to Cr ratios plot on a chondritic trendline. Current mechanisms previously proposed for the formation of accretionary lapilli during an impact event seem somewhat inadequate to explain deposition of distal accretionary lapilli resulting from impact events. A new mechanism for upper atmospheric accretion is proposed, whereby ash ejected from impact events concentrates at altitudes of neutral buoyancy, where it then accretes and is deposited later than ballistically emplaced particles. It is likely that a variety of different processes operated in the chaotic postimpact environment. Similar accretionary lapilli as in Sudbury are rare among impacts on Earth and thus deserve further study. Also, the ejecta may offer a better way to constrain the nature of the impacting body, rather than the (altered) fallback breccia within the structure.

Recently, carbon-rich microfossils were discovered in the breccias of the Onaping Formation, Sudbury impact structure; this suggests the presence of a previously unknown complex algal flora that inhabited the preimpact sea before the impact event 1.85 billion years ago at the very end of the Paleoproterozoic (Gurov et al. 2020).

Suevite

Daniele L. Pinti
Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montreal, QC, Canada

Synonyms

[Mixed breccia](#); [Suevite breccia](#); [Suevitic impact breccia](#)

Definition

A suevite or suevite breccia refers to a polymictic impact breccia with clastic matrix and mineral clasts, unshocked or in various stages of shock metamorphism, including cogenetic glassy or crystallized impact melt particles. The clasts represent the composition of the target lithologies. Initially identified in the Ries crater (Germany), it is now a generalized term commonly used to describe brecciated rocks (impactites) produced by meteorite impacts and found in several other structures, worldwide. Suevite can occur within the crater or as proximal ejecta surrounding the structure.

Sulfate Minerals

Nicholas Arndt

Emeritus Professor, ISTerre, University Grenoble Alpes, Grenoble, France

Definition

Sulfates are a class of minerals which include the sulfate ion SO_4^{2-} within their structure. Sulfate minerals occur in evaporitic environments, in hydrothermal veins, and as secondary minerals in the oxidizing zone of sulfide mineral deposits. Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) and anhydrite (CaSO_4) are common minerals in evaporitic environments; barite (BaSO_4) precipitates from hydrothermal fluids; and anglesite (PbSO_4) is an alteration product of lead sulfide ores. The identification of ► [jarosite](#), a potassium iron sulfate hydroxide, magnesium sulfates, and possible relicts of gypsum at the Meridiani Planum landing site on ► [Mars](#) is suggested to be evidence of wet, oxidizing conditions in the early history of the red planet.

Anaerobic respiration · Organic matter remineralization · Sulfur isotope effects · Anaerobic oxidation of methane

Definition

Sulfate reduction is a redox reaction in which the divalent anion sulfate (SO_4^{2-}) is reduced to

sulfide (S^{2-}) following the addition of eight electrons. This reaction can be coupled to the oxidation of other chemical species including a variety of organic compounds (e.g., acetate, pyruvate, methane) or inorganic compounds such as hydrogen (H_2). It is an important diagenetic process that oxidizes organic carbon generated by photosynthesis. Therefore, sulfate reduction is essential to regulating oxidant budgets in Earth's oceans and sediments. Sulfate reduction is one of the oldest metabolisms identifiable in the geological record as indicated by sulfur isotope signatures in sulfate- and sulfide-bearing minerals from Archean-aged rocks (see review in Fike et al. 2015).

Overview

Microbial sulfate reduction (MSR) is a form of energy metabolism catalyzed by members of the Archaeal and Bacterial domains of life (Pereira et al. 2011; Rabus et al. 2013). The reaction can be summarized as:

MSR is thermodynamically less favorable than other anoxic energy metabolisms that use terminal electron acceptors such as nitrate, manganese, or iron oxides. Nonetheless, approximately half of the organic matter in shallow marine sediments is oxidized back to inorganic carbon through sulfate reduction (Jorgensen 1982). This is due, in part, to the abundance of sulfate in seawater, where it holds thirteen times the oxidizing capacity of all oxygen in the atmosphere (Hayes and Waldbauer 2006). MSR can also be coupled to the anaerobic oxidation of methane (AOM) via a process catalyzed by communities of anaerobic

methanotrophic archaea and sulfate-reducing *Deltaproteobacteria*:

The AOM coupled to MSR was first observed at the sulfate-methane transition zone in marine sediments but has since been found in freshwater systems (see review in Knittel and Boetius 2009). MSR coupled to the AOM consumes approximately 90% of methane in diffusive marine sediments. Although MSR primarily occurs in anoxic environments, sulfate-reducing microbes have been found in oxic environments where rapid reoxidation of sulfide inhibits its accumulation. This so-called “cryptic” sulfur cycling is thought to play a role in fixed nitrogen loss from the ocean (Canfield et al. 2010; Johnston et al. 2014). In addition to being a major component of the sulfur cycle, sulfate reduction plays a key role in the global carbon, oxygen, nitrogen, iron, and other nutrient and element cycles.

Abiotic sulfate reduction to sulfide is kinetically inhibited at the low temperatures of Earth's surface conditions. As such, sulfate reduction is normally catalyzed by microorganisms using a reaction network with four key enzymatic steps (Fig. 1). The import of sulfate into the cell is the first step. This is done by sulfate transporters that operate as symporters transferring sulfate into the cytoplasm along with cations; the latter are generally protons in freshwater and sodium ions in seawater (Cypionka 1995). The second step is the activation of sulfate to an unstable intermediate adenylyl 5'-phosphosulfate (APS) by the enzyme sulfate adenylyl transferase (Sat, EC 2.7.7.4, also called ATP sulfurylase). Sulfate activation to APS requires energy derived from one molecule of adenosine triphosphate (ATP) per sulfate. The third step is the reduction of APS to sulfite

S

Sulfate Reduction,

Fig. 1 Schematic of the microbially mediated sulfate reduction pathway. All steps in the pathway are reversible. See text for definition of acronyms

(SO_3^{2-}) by adenylyl-sulfate reductase (ApsR, EC 1.8.992., also called APS reductase). The details of the final step, the reduction of sulfite to sulfide, have been the subject of much debate (see reviews by Bradley et al. 2011 and Rabus et al. 2013). Initial models invoked either a stepwise reduction of sulfite to sulfide through intermediates trithionate ($\text{S}_3\text{O}_6^{2-}$) and thiosulfate ($\text{S}_2\text{O}_3^{2-}$) or a direct six-electron reduction of sulfite to sulfide (Harrison and Thode 1958; Peck 1962). Recent work demonstrates that the reduction of sulfite to sulfide is carried out by dissimilatory sulfite reductase (Dsr), which is a multi-subunit enzyme consisting of DsrA and DsrB with the assistance of a separate sulfur transfer protein, DsrC (Santos et al. 2015). In this model, DsrAB reduces sulfite with two electrons where S^0 is bound to a reduced DsrC. After DsrC-bound S^0 dissociates from the DsrAB, the reduced cysteines of DsrC donate electrons to form a DsrC-trisulfide complex. Finally, the DsrC-trisulfide reacts with the membrane-bound DsrMKJOP complex, receiving the final two electrons, releasing H_2S , and re-reducing DsrC. These final steps of DsrC scavenging S from DsrAB and the reaction with DsrMKJOP were only recently recognized and complete core biochemistry of MSR (Santos et al. 2015). The reaction with DsrC/DsrMKJOP couples terminal sulfide production to membrane-bound electron transport and, critically, energy conservation.

The fractionation of sulfur isotopes during microbial sulfate reduction influences sulfur isotope signatures of sulfate and sulfide in both open marine and sediment pore waters. Those isotopic signatures can then be preserved in sulfate and sulfide minerals that are used in global biogeochemical models to reconstruct atmospheric O_2 levels (e.g., Kump and Garrels 1986) or environmental change (e.g., Leavitt et al. 2013) throughout Earth history. Sulfur isotopes are expressed in delta notation ($\delta^{34}\text{S}$) as permil (‰) deviations in the ratio of ^{34}S to ^{32}S from the Vienna-Canyon Diablo Troilite standard. The theoretical equilibrium sulfur isotope fractionation between sulfate and sulfide is approximately 70‰ at 25 °C (Farquhar et al. 2003). Fractionations approaching this limit have been observed

experimentally in batch and continuous cultures of sulfate-reducing bacteria grown at very slow sulfate reduction rates (Sim et al. 2011; Leavitt et al. 2013). Several models have been proposed to explain these fractionations (reviewed in Bradley et al. 2016). Each of these models suggests that critical parameters affecting fractionation include ambient sulfate and sulfide concentrations, cell-specific sulfate reduction rate, and the reversibility in each step of the sulfate reduction pathway. Although the general trend is that sulfur isotope fractionation is inversely related to sulfate reduction rate, transport processes (e.g., Chanton et al. 1987) and reservoir effects (e.g., Gomes and Hurtgen 2013) also influence the offset between $\delta^{34}\text{S}$ values of sulfate and sulfide minerals (i.e., barite or calcium-sulfate minerals and pyrite, respectively) because they determine if $\delta^{34}\text{S}$ patterns can be described by open-system versus closed-system models (i.e., Rayleigh fractionation). Open-system models, which favor full expression of biological sulfur isotope fractionations, are more appropriate for low-oxygen, anoxic, or euxinic settings because the sulfate reservoir is more likely to be well-mixed. Well-oxygenated settings where sulfate reduction occurs deep in the sediment are more similar to closed-systems, where progressive consumption of the sulfate reservoir inhibits the expression of biological sulfur isotope fractionation. Thus, sulfur isotope signatures can be used to investigate sulfur cycling processes in modern and ancient settings.

The sedimentary record of sulfate reduction extends through the majority of Earth history and tracks the oxygenation of its surface environments. The earliest evidence for sulfate reduction comes from $\delta^{34}\text{S}$ values of microscopic pyrite grains, which are 21‰ lower than associated barites from the 3.5 Ga Dresser Formation of the Warrawoona Group, Pilbara Craton (AU) (Shen et al. 2001). This 21‰ fractionation is consistent with high rates of microbial sulfate reduction, given the low temperature origin of these sediments and intimate association of pyrite grains with organic carbon. Despite this early evidence for microbial sulfate reduction, $\delta^{34}\text{S}$ variability of sulfides extracted from bulk sedimentary rocks is

mutated to below 10‰ for the majority of the Archean (Canfield and Farquhar 2009), although individual pyrite grains have larger $\delta^{34}\text{S}$ variability (e.g., Fischer et al. 2014). After the Great Oxidation Event at ~2.4 Ga, increasing marine sulfate concentrations led to an increase in the range of sedimentary sulfide $\delta^{34}\text{S}$ values of up to ~50‰ because the reservoir effect no longer limited preserved fractionation values. Contemporaneous with increased oxygenation, a second rise in the range of sedimentary sulfide $\delta^{34}\text{S}$ values to >70‰ is recorded in the late Neoproterozoic (see Lyons et al. 2014 for a review).

In summary, sulfate reduction is a ubiquitous microbially mediated process in marine and freshwater systems where the reduction of sulfate to sulfide is coupled to the oxidation of organic matter, hydrogen, or methane. Sulfate reduction plays an important role in the global biogeochemical cycles of sulfur, carbon, and oxygen on Earth now and over billions of years and therefore may also play an important role in these cycles on other Earth-like planets.

The biooxidation of sulfur concerns the biological (enzymatic) pathway that extracts energy from chemically reduced forms of sulfur, typically producing sulfate as a by-product of metabolism.

History

The biooxidation of sulfide was first demonstrated by Winogradsky (1887), who fed a culture of *Beggiatoa* with H_2S , demonstrating the formation of elemental sulfur granules. Nathansohn (1902) first isolated a member of the bacterial genus *Thiobacillus*, noted for its ability to oxidize elemental sulfur, which was followed by Waksman and Joffe (1921) who isolated *Thiobacillus*

thiooxidans, an acidophilic sulfur-oxidizing bacterium.

Overview

The oxidation of sulfur can proceed through a range of potentially complex biogeochemical and abiotic reaction pathways (Schmidt et al. 1987). For example, the biogeochemical oxidation pathway for “sulfur,” producing sulfate, can begin with diverse substrates, including hydrogen sulfide (H_2S ; link to *Sulfate reduction*), elemental sulfur (S^0), thiosulfate ($\text{S}_2\text{O}_3^{2-}$), and tetrathionate ($\text{S}_4\text{O}_6^{2-}$) (see reactions 1–4). In these reactions, the production of sulfate reflects the complete oxidation of each substrate, where all of the available energy has been “extracted.” While sulfur oxidation is most active under aerobic conditions (Knickerbocker et al. 2000), phototrophic purple and green sulfur bacteria can oxidize H_2S to S^0 or SO_4^{2-} (reactions 5 and 6) under anaerobic conditions via anoxygenic photosynthesis (Pfennig 1975; link to *Anaerobic photosynthesis*). They can also utilize other reduced sulfur compounds such as thiosulfate and sulfite.

1. $\text{H}_2\text{S} + \frac{1}{2} \text{O}_2 \rightarrow \text{S}^0 + \text{H}_2\text{O}$
2. $\text{S}^0 + \frac{1}{2} \text{O}_2 + \text{H}_2\text{O} \rightarrow \text{SO}_4^{2-} + 2 \text{H}^+$
3. $\text{S}_2\text{O}_3^{2-} + 2 \text{O}_2 + \text{H}_2\text{O} \rightarrow 2 \text{SO}_4^{2-} + 2 \text{H}^+$
4. $\text{S}_4\text{O}_6^{2-} + 3\frac{1}{2} \text{O}_2 + 3 \text{H}_2\text{O} \rightarrow 4 \text{SO}_4^{2-} + 6 \text{H}^+$

The biooxidation of sulfur does not necessarily proceed through the direct oxidation pathways seen and can be closely linked to sulfur reduction under “aerobic” (Norlund et al. 2009) and anaerobic conditions (Pfennig 1975). The oxidation of sulfur can also occur chemically via ferric iron oxidation, catalyzing the formation of sulfate via an abiotic mechanism (reaction 7), with the biogeochemical oxidation of iron (link to *Iron oxidation*) accelerating this reaction (Singer and Stumm 1970).

This summary reaction, transferring 14 electrons from pyrite- (FeS_2) producing sulfate as a by-product, ignores the diverse sulfur intermediates, for example, thiosulfate, in this acid system. Under acid conditions, the biooxidation of sulfur is further complicated by additional abiotic processes, for example, the disproportionation of thiosulfate into elemental sulfur and sulfurous acid (reaction 8).

Sulfide Oxidation, Fig. 1 Photographs of the Rio Tinto River, Spain (a), and Basque Lake #2 Canada (b) highlight the presence of jarosite ($\text{KFe}_3(\text{OH})_6(\text{SO}_4)_2$; see Loiselle et al. 2018; link to *Iron oxidation, Rio Tinto*) and epsomite

($\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$; see Foster et al. 2010), respectively, two sulfate-bearing minerals that can entrap bacteria on Earth, making them prime targets in the search for inorganic and organic, extraterrestrial biomarkers

In addition to the production of a range of aqueous and solid (elemental) sulfur intermediates, there are a wide range of sulfate minerals such as jarosite, formed under acid conditions, and epsomite, which is found in weathered terrains where the acid from sulfur oxidation (reactions 2–4) has been buffered by ultramafic materials, releasing magnesium (Mg^{2+}) (Fig. 1).

From an astrobiology perspective, differentiating between these biotic versus abiotic processes is critical to identifying the biological contributions to these reactions and to the search for life beyond Earth. Sulfate is a particularly important target given the high sulfate content (~10–15%) of Martian soil (Clark et al. 1976). The formation of sulfate minerals during bacterial colonization of meteorites on Earth (Tait et al. 2017) raises interesting questions about the potential for these materials on Mars.

Definition

A sulfidic ocean defines a condition where dissolved sulfide is found stably in measurable concentrations within the marine water column. Such waters contain no dissolved oxygen but are typically found below the oxygen-containing region of the upper water column. Dissolved sulfide may or may not extend to the seafloor.

Overview

Sulfidic water-column conditions are found in permanently stratified basins such as the Black Sea and the Cariaco Basin, and in numerous stratified fjords and other coastal embayments. Examples include Mariager Fjord in Denmark, Saanich Inlet in the USA, and Byfjorden in Sweden. Sulfide also accumulates in deep depressions such as the Gotland Deep in the Baltic Sea. Sulfide accumulates when the flux of oxygen by advection and diffusion is outpaced by the flux of reactive organic carbon from sinking marine biomass. The oxidation of the reactive carbon consumes all the oxygen and then the available nitrate, after which sulfate reduction ensues producing sulfide. Sulfide reacts with available iron oxides, and sulfide accumulates when the iron oxides are consumed. Although a rare condition today, if there is insufficient sulfide to consume the reactive iron oxides, dissolved ferrous iron may accumulate creating ferruginous water column conditions. Sulfidic conditions are often associated with enhanced water-column stratification, as this limits the oxygen flux.

While they are oxygen-free and thermally stratified, sulfide is rare in oxygen minimum zones of the global ocean. This is due to a feedback loop involving the nitrogen cycle. This feedback loop checks the microbial loss of nitrate to N_2 gas in the oxygen-free waters, maintaining the waters nitrate-rich and sulfide-free. Sulfide can accumulate if ► [nitrogen fixation](#) (microbial conversion of N_2 to organic nitrogen) balances the loss of nitrate to N_2 , but for reasons not well understood, nitrogen fixation is limited in these regions.

Sulfidic ocean conditions were very rare or absent in the distant geologic past when the Earth's atmosphere was anoxic. With no oxygen, mineral sulfides were not oxidized to sulfate on land, limiting the delivery of sulfate to the oceans and thereby limiting sulfate reduction in the oceans. The earliest reported sulfidic marine water column was 2.5 billion years ago in association with an early rise in atmospheric oxygen concentrations. Sulfidic water column conditions became more prevalent after this and from about

1.8 to about 1.0 billion years ago, sulfidic waters were not uncommon, sharing marine anoxic waters with ferruginous conditions. For reason not well understood, sulfidic marine waters became rare in the time window of about 1.0–0.55 billion years ago when marine anoxic waters were dominantly ferruginous.

Over the last 550 million years, anoxic marine waters were far more often sulfidic than ferruginous, likely due to a rise in seawater sulfate concentrations driving more sulfate reduction under anoxic water column conditions. Overall, however, marine anoxia has been less extensive over the last 550 million years likely due to elevated atmospheric oxygen levels. Still, major episodes of water column sulfide accumulation have been documented from sedimentary rocks throughout this period, and at least during some periods of time, sulfidic conditions were much more extensive than today. The frequency and intensity of water column sulfide accumulation over the last 550 million years have likely resulted from an interplay between atmospheric oxygen levels, paleogeography, and climate.

Chemical Formula

S

Definition

Sulfur is a chemical element with the atomic number 16 denoted by the symbol S. It is a naturally

abundant, multivalent nonmetal. In its native form, at room temperature and pressure, sulfur is a soft bright yellow crystalline solid. In nature, it can be found as the pure element and in the form of sulfide and sulfate minerals. It is found in two of the coded protein amino acids: ► [cysteine](#) and ► [methionine](#).

Overview

The strong smell of sulfur is usually due to the presence of ► [hydrogen sulfide](#) (H₂S) or organosulfur compounds. Elemental sulfur is fairly insoluble in water. Common oxidation states of sulfur include −2, +2, +4, and +6. Sulfur forms stable compounds with most elements. Sulfur forms more than 30 solid allotropes, more than any other element. Besides S₈, several other rings are known. Elemental sulfur is an equilibrium mixture of S₈, S₇, and small amounts of S₆.

Sulfur is unusual in that its viscosity in its molten state, unlike most other liquids, increases above temperatures of 200 °C (392 °F) due to the formation of polymers. Molten elemental sulfur is dark red above this temperature. At higher temperatures, its viscosity decreases as depolymerization occurs. The distinctive colors of Jupiter's volcanic moon, Io, are from various forms of molten, solid, and gaseous sulfur.

Sulfur has 25 known isotopes, 4 of which are stable – ³²S, ³³S, ³⁴S, and ³⁶S – with natural terrestrial abundances of 95.02%, 0.75%, 4.21%, and 0.02%, respectively. Aside from ³⁵S, all of the radioactive isotopes of sulfur are short-lived.

Common naturally occurring sulfur compounds include sulfide minerals such as pyrite (iron sulfide, FeS), galena (lead sulfide, PbS), and sphalerite (zinc sulfide, ZnS), and sulfate minerals, such as gypsum (calcium sulfate, CaSO₄ · H₂O) and barite (barium sulfate, BaSO₄). Sulfur occurs naturally in volcanic emissions.

Sulfur is present in many types of meteorites. Ordinary chondrites contain an average of 2.1% sulfur, and carbonaceous chondrites may contain

as much as 6.6% sulfur. Sulfur in meteorites is normally present as troilite (FeS), but other sulfides are found in some meteorites, and carbonaceous chondrites contain free sulfur, sulfates, and possibly other sulfur compounds, including organosulfonates.

Sulfur is created in extremely large, extremely hot (nuclear temperature over 2.5 billion kelvin) stars, by the fusion of silicon with helium.

Organosulfur compounds include thioethers (with the generic formula $R - S - R$), thiols (also known as mercaptans, with the generic formula $R - SH$), thiolates (the conjugate bases of thiols, with the generic formula $R - S^-$), sulfoxides (with the generic formula $R - S(=O) - R'$), and sulfones (with the generic formula that has the form $R - S(=O)_2 - R'$).

Many organisms are able to use sulfur in its various redox states as a source of energy. Some bacteria use hydrogen sulfide (H_2S) in the place of water as an electron donor in the form of photosynthesis in which oxygen is the electron acceptor. The photosynthetic green and purple sulfur bacteria use elemental oxygen to oxidize hydrogen sulfide to elemental sulfur. Some bacteria which live around deep-sea hydrothermal vents oxidize hydrogen sulfide in this way. Sulfur bacteria use sulfate as an electron acceptor instead of oxygen and reduce various oxidized sulfur compounds to sulfides.

There are numerous sulfur-containing metabolites which are important in biochemistry, most notably the protein amino acids methionine and cysteine. Glutathione is an important sulfur-containing compound which plays a cellular role as a source of reduction potential. Several coenzymes have $-SH$ moieties to handle reactions involving acyl-containing biochemicals, for example, coenzyme A and alpha-lipoic acid.

Some theoretical models for the origin of life have emphasized the role of sulfur compounds, for example de Duve's thioesters, with a role in an early energy transduction mechanism, or the anaerobic synthesis of pyrite from hydrogen sulfide and ferrous sulfide as the earliest source of energy and electron in primitive metabolisms as postulated by Wächtershäuser.

atomic S up to 9 atom molecules (CH₃CH₂SH) (see Table 1). They are routinely observed in a wide variety of astrophysical objects from extragalactic sources to our own solar system. Commonly used to constrain the physical conditions of the environment in which they thrive, the S-chemistry also plays an important role in the formation of life building blocks (Chen et al. 2015) and planet habitability (Ranjan et al. 2018; Ruf et al. 2019). Sulfur is thus an important element linking the physics, the chemistry, and ultimately the biology of its environment.

Overview

Despite all the astronomical observations of sulfur-bearing species, the chemistry of sulfur in space remains one of the least understood. This is mainly due to the fact that we still do not know the nature and identity of its chemical reservoir(s). In the diffuse interstellar medium (ISM) and photon-dominated regions (PDR), the total amount of sulfur is close to the value measured in the Sun photosphere of S/H $\sim 1.5 \times 10^{-5}$ by Asplund et al. (2009) (e.g., Goicoechea et al. 2006; Howk et al. 2006). This is in contrast with dense molecular gas, where the total amount of sulfur is found to be strongly depleted. No more than $\sim 1\%$ of the sulfur cosmic abundance is observed in the gas phase (e.g., Tieftrunk et al. 1994; Wakelam et al. 2004; Vastel et al. 2018). Therefore, one can wonder where does the sulfur from diffuse to dense gas

go. A commonly accepted hypothesis is that most of the sulfur depletes onto icy grain mantles with decreasing temperature and increasing density which characterize the transition from diffuse to dense gas (e.g., Ruffle et al. 1999; Vidal et al. 2017; Laas and Caselli 2019). However, only $\sim 4\%$ of the solar abundance of sulfur has been detected in interstellar ices so far (Boogert et al. 2015 and reference therein). Therefore, the nature and identity of the sulfur reservoir(s) in the ISM remains an open question.

Sulfur-bearing species are ubiquitous in the solar system, especially in the diverse relics of our own planet-forming disk such as comets and meteorites but also on planets and their satellites (e.g., Calmonte et al. 2016; Lellouch et al. 2007). While nine S-bearing species were detected in cometary atmosphere from remote observations during the past two decades – namely, H₂S, CS, SO, SO₂, OCS, H₂CS, NS, atomic S, and S₂ (Meier and A'Hearn 1997; Bockelee-Morvan et al. 2004; Biver et al. 2016) – the Rosetta mission on comet 67P/Churyumov-Gerasimenko (67P/C-G hereafter) enlarged the discovery of cometary sulfur-bearing molecules. Measurements of the coma revealed the presence of S-molecules commonly detected in the gas-phase ISM and previously found in other comets, such as H₂S, atomic S, SO, SO₂, OCS, H₂CS, and tentatively CS and NS. Furthermore, multi-sulfuretted molecules, not yet found in the ISM, such as CS₂, S₃, and S₄ (Le Roy et al. 2015; Calmonte et al. 2016), were also detected as well

as complex S-molecules such as CH_3SH and $\text{C}_2\text{H}_6\text{S}$. The latter has two isomers, ethanethiol (i.e., $\text{CH}_3\text{CH}_2\text{SH}$, also known as ethyl mercaptan and only detected in Orion KL so far (Kolesnikova et al. 2014)) and dimethyl sulfide ($(\text{CH}_3)_2\text{S}$, not yet detected in any other astrophysical object). However, the 67P/C-G measurements did not allow to distinguish the proportion of these two isomers. Studying the S-chemistry in the evolutionary stages leading from the quiescent ISM to the formation of planetary system is therefore a pivotal step to giving a window into the chemical origins of our own solar system while also, and as importantly, to help us better understanding the cycle and role of sulfur in astrochemistry. This is especially important to predict what, and in which quantities, S-compounds are expected on nascent planets assembling at different disk radii around different types of stars.

Basic Methodology

Millimeter and sub-millimeter astronomy has been the principal source of S-bearing molecules discovery in space. In the twenty-first century, the unprecedented high sensitivity and spectral and spatial resolutions of the latest generation of radio-telescopes has helped to considerably enlarge this discovery. In particular, it has allowed us to start uncovering the chemistry of pivotal astrophysical objects in the evolution from molecular clouds to the formation of planetary systems, proto-planetary disks.

Providing both the volatile (gas and ice) and refractory (dust) reservoirs for planet formation, these gas- and dust-rich disks orbiting young stars are the birthplace of planetary systems. Therefore, the chemical composition of planets and by extension their hospitality to life are intimately linked to both the chemical composition and the structure of the disk in which they form. Furthermore, these pivotal astrophysical objects are vertically stratified into atmospheres, warm molecular layers, and cold mid-planes, which are analogs to PDR, luke-warm molecular clouds, and cold dense cores, respectively (Aikawa et al. 2002). Recent sulfur-bearing species observations in each of these three

types of analog astrophysical environments (e.g., Drozdovskaya et al. 2018; Vastel et al. 2018; Riviere-Marichalar et al. 2019) have revived interest in the global quest for understanding the cycle of sulfur chemistry from molecular cloud to exoplanetary systems and are timely for the exploration of the sulfur chemistry in proto-planetary disks. In this context, and for the remainder of this methodology section, we focus on these pivotal astrophysical objects that constitute perfect testbeds to study the cycle of sulfur astrochemistry.

Among the approximately 30 molecules detected in proto-planetary disks so far (http://astrochymist.org/astrochymist_disks.html), seven contain sulfur. These include CS (Dutrey et al. 1997) and SO (Fuentes et al. 2010), which were detected during the past two decades, and H_2S (Phuong et al. 2018), H_2CS , ^{13}CS , C^{34}S (Le Gal et al. 2019) and SO_2 (Booth et al. 2021), detected within the past few years, thanks to the significant sensitivity improvements made in radio-interferometry instruments. However, these six molecules remain a small fraction ($\sim 15\%$) of the collection of sulfur-bearing molecules detected in space (~ 35 ; see Table 1). CS is the most readily detected S-bearing species in proto-planetary disks (Dutrey et al. 1997; Fuentes et al. 2010; Guilloteau et al. 2016; Le Gal et al. 2019). SO, was the sole oxygenated, sulfur-bearing species detected in proto-planetary disks until the very recent detection of SO_2 in one disk (Booth et al. 2021). Remarkably, SO has only been found toward a few young disks with signs of active accretion (Fuentes et al. 2010; Guilloteau et al. 2013; Guilloteau et al. 2016; Pacheco-Vazquez et al. 2016; Booth et al. 2018). H_2S has long been thought to be a main sulfur reservoir and is a major sulfur carrier in comet 67P/C-G (Calmonte et al. 2016). However, it was only detected recently in a massive proto-planetary disk with a CS/ H_2S gas-phase column density ratio of ~ 20 (Phuong et al. 2018), after unsuccessful search in a handful of other proto-planetary disks (Dutrey et al. 2011). While additional H_2S observations in such disks are required to draw firm conclusions, this result casts doubt on the importance of H_2S in disk gas-phase S-chemistry

and has revived interest in the quest to identify the sulfur reservoir in these environments (e.g., Kama et al. 2019).

In proto-planetary disks, the abundance and spatial distributions of gas and solids is supposed to determine the chemical composition of the future planets that will eventually form within them and ultimately the architecture the emergent planetary systems, although the latter remains to be characterized. However, the observations provide only “snapshots.” Theoretical studies on the formation, excitation, and destruction of the molecules observed are therefore essential to interpret the observations. Such studies constitute the roots for the development of robust and precise chemical reaction networks, which are themselves key ingredients of astrochemical models. Such models are indeed built to compute the abundances of each of the molecular species contained in a given chemical network. Current chemical networks, combining gaseous and solid phase chemistry, globally explain the formation of the molecules observed. However, they do not always explain their abundances! This parameter is however crucial in order to interpret and develop observable molecular signatures of various astrophysical phenomena, such as planetary formation. It is therefore essential to develop the accuracy and precision of these chemical networks; however, as of today, only 5–10% of the reaction rates involved in the networks of several thousand reactions come from calculations or experimental measurements. It is thus crucial to keep developing these networks, which requires to build interdisciplinary collaborations in between theoretical chemists, experimentalists, and astrophysicists. In particular, for the case of proto-planetary disk modeling, current disk astrochemical models are still incomplete and lack accuracy about several crucial points. For instance, we still do not know the initial conditions of the chemistry, i.e., its composition, its elemental abundances, and also the initial physical conditions under which the chemistry initiates. We also do not know how stellar radiation impacts on both the disk chemistry and the chemical structure we can now capture with the latest generation of telescopes, nor do we know what the interplay is between chemistry,

disk dynamics, and planet formation. Improving these models is thus central to properly interpret the molecular gas observations we presently have access to in proto-planetary disks.

Key Research Findings

An example is the recent detection of H_2CS in a proto-planetary disk, which led to a $\text{H}_2\text{CS}/\text{CS}$ gas-phase column density ratio of $\sim 1/3$. This unexpectedly high ratio is an important new result for two reasons. Firstly, it suggests that a substantial portion of the volatile sulfur in disks may be in organic form (i.e., $\text{C}_x\text{H}_y\text{S}_z$). Secondly, it revealed some tensions between models and observations suggesting an incomplete theoretical understanding of the sulfur chemistry in disks (Le Gal et al. 2019). Pursuing studies of sulfur chemistry is therefore crucial to better constrain current astrochemical models, which in turn constitute also important tools to indirectly inform us on the potential compositions of unseen reservoirs such as the ice reservoir hosted on dust grains.

Future Directions

As of today, we still do not know what the major sulfur reservoir in proto-planetary disks is and in which form it resides. However, this is a fundamental parameter to constrain, not only to solve current modeling tensions such as the one found to interpret the high $\text{H}_2\text{CS}/\text{CS}$ ratio recently observed in proto-planetary disks but also because, more generally, many S-bearing species are observed in comets and do play an important role in the building up of prebiotic molecules and on planet habitability (Chen et al. 2015; Ranjan et al. 2018; Ruf et al. 2019).

Recently, based on the abundances of B star photospheres, Kama et al. (2019) found that ~ 81 – 97% of the S-budget should be locked in disk refractory material. Following the findings of Keller et al. (2002), the former authors proposed that most of the sulfur should be locked in the form of solid FeS in disks rather than in polymeric S_n ($n = 2$ – 8) molecules, where the

latter has been proposed for decades as a potential hidden S-reservoir in the ISM (e.g., Wakelam et al. 2004). However, the observations of solid FeS have not yet been confirmed in disks (Keller et al. 2002), whereas hints of solid S_n were recently reported on the comet 67P/C-G with the detections of S_2 , S_3 , and S_4 from the Rosetta mission (Calmonte et al. 2016), although these detections constitute only $\sim 0.2\%$ of the total detected S-content of 67 P/C-G.

OCS is another promising S-reservoir. It is the only S-bearing molecule unambiguously detected in ice mantles so far (see Boogert et al. (2015) and reference therein). Furthermore, astrochemical shock modeling benchmarked to protostellar shock observations predicted that OCS ices represent $\geq 50\%$ of the sulfur reservoir (e.g., Podio et al. 2014). The latter is therefore a promising organic S-reservoir to interpret the high H_2CS/CS ratio observed in disks. In current astrochemical models (e.g., those based on the Kinetic Database For Astrochemistry – <http://kida.astrophy.u-bordeaux.fr>), H_2CS is mainly formed from gas-phase reactions, the neutral-neutral reaction of atomic S and CH_3 , and the electronic dissociative recombination of H_3CS^+ , originating from the $S^+ + CH_4$ reaction. It is also formed, for a smaller contribution, from gas-grain chemistry where H_2CS is produced from successive hydrogenation on icy dust mantles and released for $\sim 1\%$ in the gas phase by chemical reactive desorption. However, currently, there is no consideration of OCS grain surface processing that could lead to the formation of organo-sulfur compounds such as H_2CS which, perhaps, would provide a better match with observations. To further explore this hypothesis, laboratory experiments and theoretical chemical calculation for such mechanisms are needed. The nature and identity of the reservoir of sulfur could also be changing throughout the disk, i.e., from the inner to the outer regions and/or from the atmospheric layer, where UV photons are driving the chemistry, to the mid-plane, where most of the molecules are frozen onto icy dust grain mantles. Resolved observations of the distribution of sulfur-bearing molecules in disks are thus required for further investigations, which could also allow us to test if and how any chemical

inheritance from molecular cloud stage to the planet-forming environment could be captured.

Sulfur Cycle

José Luis Sanz

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

The sulfur cycle, like the ► [biogeochemical cycles](#) of other elements, includes a series of oxidation and reduction stages of sulfur that are principally biotic and performed by microorganisms. Under certain pHs and redox potentials, some reactions of the sulfur cycle take place in the absence of microorganisms.

Overview

The sulfur cycle integrates and interconnects the different components of an ecosystem (soil, rock,

sediment, aquatic phase, and atmosphere). Sulfur is present as organic sulfur (in amino acids, coenzymes, etc.) and inorganic sulfur: sulfides (S^{2-}), elemental sulfur (S^0), sulfates (S^{6+}), and a series of intermediaries of minor environmental relevance. Sulfate (SO_4^{2-}) is the major bioavailable form in nature, and is particularly abundant in marine environments, because elemental sulfur and hydrogen sulfide (H_2S) are of biological or geothermic origin and metal sulfides (MeS) are insoluble.

The sulfur cycle is complex, involving aerobic and anaerobic, auto- and heterotrophic, and chemo- and photosynthetic microorganisms. In anaerobic settings, primarily in aquatic sediments and to a lesser extent in soils (generally acidic and stagnant) or the digestive tracts of warm-blooded animals, sulfur- and sulfate-reducing bacteria (SRB) reduce sulfur and sulfates, respectively, to hydrogen sulfide. Phylogenetically, these bacteria belong to the class delta-*Proteobacteria* (*Desulfovibrio*, *Desulfuromonas*) and the order *Clostridiales* (family *Peptococcaceae*: *Desulfotomaculum*, *Desulfosporosinus*). The ► [reduction](#) takes place in an ► [anaerobic respiration](#) in which oxidized forms of sulfur (dissimilative reduction) act as electron acceptors for the oxidation of simple organic compounds (acetate, lactate, etc.) or H_2 , yielding H_2S as a final product. Some ► [archaea](#) like *Archaeoglobus* also carry out this process. Some species belonging to genera such as *Clostridium* or *Alteromonas* reduce thiosulfate ($S_2O_3^{2-}$) to H_2S . Alternatively, sulfate is converted into phosphoadenosine 5'-phosphosulfate (PAPS) by many bacteria and plants. In the form of PAPS, sulfur is used in the biosynthetic processes of living organisms (assimilative reduction).

H_2S , either released by SRB or of geothermal origin, can be used by bacteria, such as purple (*Chromatium*) or green (*Chlorobium*) sulfur bacteria, that carry out anoxygenic photosynthesis typically in anaerobic conditions such as deep aquatic systems or microbial biofilms. In both cases, H_2S acts as an ► [electron donor](#), giving rise to elemental sulfur. H_2S can also be used by bacteria that carry out aerobic anoxygenic photosynthesis (*Erythromonas*, *Roseobacter*). In aerobic environments, H_2S is used by

chemolithotrophic sulfur-oxidizing bacteria, such as *Thiobacillus* or *Thiomicrospira*, that accumulate extracellular elemental sulfur granules. In *Thiovulum* or filamentous bacteria like *Beggiatoa*, elemental sulfur accumulates inside their cells. In both cases, the sulfur can be further oxidized to sulfate.

Some sulfur-dependant thermophilic archaea, belonging to the order *Sulfolobales*, also carry out the oxidation of H_2S or S^0 to sulfate in the presence of oxygen (*Sulfolobus*, *Acidianus*). In the absence of O_2 , a great number of thermophilic archaea – both *Crenarchaeota* (*Thermoproteus*, *Desulfurococcus*, *Pyrodictium*) and *Euryarchaeota* (*Thermococcus* or some methanogens) – display autotrophic, myxotrophic, or heterotrophic growth during which S^0 is reduced to H_2S (although methanogens obtain no energy in the process).

Under certain circumstances, such as in the presence of oxygen and in neutral pH, H_2S is oxidized rapidly and abiotically to elemental sulfur.

Sulfur Hydrides in the Interstellar Medium

William M. Irvine

Department of Astronomy, University of Massachusetts Amherst, Amherst, MA, USA

Synonyms

H_2S ; [Hydrogen sulfide](#); [Mercapto radical](#); S_2H ; SH ; SH^+ ; [Sulfaniumylidene](#); [Sulfanyl](#); [Sulfanylium](#)

Definition

Three neutral hydrides of sulfur, H_2S , S_2H , and SH , and also the cation SH^+ , have been detected in the interstellar medium by astronomers. Sulfur hydrides are important in many origins of life models, and two of the protein amino acids used by terrestrial life contain sulfur (cysteine and methionine).

History

Whereas H_2S was one of the first triatomic molecules detected in interstellar molecular clouds (Thaddeus et al. 1972), the identification of SH^+ (Menten et al. 2011), SH (Neufeld et al. 2012), and S_2H (Fuente et al. 2017) have been much more recent. Although H_2S , S_2H , and SH^+ were observed using ground-based radio telescopes,

radio astronomers used the SOFIA airborne observatory to detect SH (for references, see ► [“Molecules in Space”](#)).

Sulfur Isotopes

James Farquhar

Department of Geology, University of Maryland,
College Park, MD, USA

Keywords

Great oxygenation event · Isotopes · Isotopic ratio · Sulfates · Sulfides

Definition

Sulfur is a relatively common element in the Solar System and on Earth. It has four relatively

abundant, naturally occurring, stable isotopes with masses of approximately 32, 33, 34, and 36 atomic mass unit (amu). It has a rich chemistry, and reactions involving sulfur compounds occur in the solid, liquid, and gaseous envelopes of Earth and other planets. It occurs in a variety of valence states ranging from +6 to −2, and as a result, sulfur is used in a variety of biological capacities.

Overview

Sulfur compounds are used as an energy source for metabolic activity (catabolism) by a variety of bacteria and archaea that draw upon redox transformations, using oxidized species as electron donors and reduced species as electron acceptors. Sulfur compounds are used as important electron acceptors for anoxygenic ► [photosynthesis](#) by green and purple sulfur bacteria. Sulfur is a constituent of both essential (► [methionine](#)) and non-essential (► [cysteine](#)) amino acids. Sulfur compounds are involved in photochemical reactions in the atmosphere, and some of these reactions can be quite complex with transformations involving a variety of bound and unbound states. The variety of bonding environments, reaction pathways, and the presence of odd and even mass nuclei that have a relatively large difference in vibrational potential energy also, ultimately, contribute to a rich isotopic chemistry.

By convention, sulfur isotope compositions are described using delta notation ($\delta^{34}\text{S}$, $\delta^{33}\text{S}$, and $\delta^{36}\text{S}$). This notation describes the deviation of an isotope ratio in a sample relative to that in an international reference material (V-CDT) and is generally expressed in permil.

A second type of notation, capital delta notation ($\Delta^{34}\text{S}$, $\Delta^{33}\text{S}$, and $\Delta^{36}\text{S}$), is used to describe the difference between the isotopic compositions of two materials expressed in delta notation. For $^{34}\text{S}/^{32}\text{S}$, $\Delta^{34}\text{S}$ is the arithmetic difference between the $\delta^{34}\text{S}$ of two materials (e.g., $\delta^{34}\text{S}_{\text{Material} - a} - \delta^{34}\text{S}_{\text{Material} - b}$), but for $^{33}\text{S}/^{32}\text{S}$ and $^{36}\text{S}/^{32}\text{S}$, the $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ describe the arithmetic difference between a measured $\delta^{33}\text{S}$ and $\delta^{36}\text{S}$ and a $\delta^{33}\text{S}$ and $\delta^{36}\text{S}$ that is predicted on the basis of the measured

$\delta^{34}\text{S}$. Following this convention, $\Delta^{33}\text{S} = \delta^{33}\text{S} - [(1 + \delta^{34}\text{S})^{0.515} - 1]$ and $\Delta^{36}\text{S} = \delta^{36}\text{S} - [(1 + \delta^{34}\text{S})^{1.90} - 1]$. The quantities $[(1 + \delta^{34}\text{S})^{0.515} - 1]$ and $[(1 + \delta^{34}\text{S})^{1.90} - 1]$ are approximately equal to the values of $\delta^{33}\text{S}$ and $\delta^{36}\text{S}$ that would be predicted for a single-step equilibrium isotope effect. The $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ therefore describe deviations from an equilibrium reference frame that is anchored by the compositional reference frame, V-CDT.

The term *isotope effect* is used to describe a change in isotope ratios that is produced by a physical or a chemical process. We use the term *fractionation factor* (α) to quantify the change in isotope ratios produced by an isotope effect (e.g., $^{34}\alpha_{a-b} = (^{34}\text{S}/^{32}\text{S})_{\text{substance } a} / (^{34}\text{S}/^{32}\text{S})_{\text{substance } b}$). The term *fractionation* is used to describe an observed difference in the isotope ratio of sulfur in two reservoirs, and a *discrimination coefficient* ($\Sigma = \alpha - 1$) is used to describe the change in isotope ratios produced by one or more processes with associated isotope effects. In this context, there are a number of different types of physical and chemical processes that generate isotope effects, and some of these produce significant variations for $\delta^{34}\text{S}$ but not for $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$, while others produce significant variations for all three. Isotope effects have been grouped into several categories. These include (1) *classical or equilibrium isotope effects* (EIE) that arise principally because of differences in vibrational potential energy and that produce significant variations for $\delta^{34}\text{S}$ but not for $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$; (2) *nuclear volume effects* (NVE) that arise because differences in the size and shape of the nucleus influence the nuclear charge distribution and may have an effect on the potential energy surfaces of bonding for different isotopes and that produce other types of variations for $\delta^{34}\text{S}$, $\Delta^{33}\text{S}$, and $\Delta^{36}\text{S}$; (3) *kinetic isotope effects* (KIE) that may in some cases produce other types of variations for $\delta^{34}\text{S}$, $\Delta^{33}\text{S}$, and $\Delta^{36}\text{S}$ and that arise because factors other than vibrational energy, such as nuclear spin, or level matching between bound and unbound states, or molecular symmetry, control rates of reactions involving molecules containing some isotopes more than they do the rates of reactions for molecules containing other isotopes;

and (4) other *physically controlled isotope effects* that reflect the operation of physical processes such as buoyancy, gravitation, kinetic energy, and mixing processes and that produce other types of variations for $\delta^{34}\text{S}$, $\Delta^{33}\text{S}$, and $\Delta^{36}\text{S}$.

Sulfur isotope compositional variations reflect different types of isotope effects that are relevant at different times in the history of Earth and other planets and that are relevant for astrobiology. These include, but are not limited to, (1a) an observation that the range of $\delta^{34}\text{S}$ is small in the oldest terrestrial rocks and becomes larger in samples that are younger in age; (1b) an observation that there are some ancient rocks (older than $\sim 3,000$ million years old (Ma)) that exhibit larger ranges of variability for $\delta^{34}\text{S}$; (1c) an observation that the average values for $\delta^{34}\text{S}$ of sedimentary pyrite are generally near zero or slightly positive until about 550 Ma when they became negative; (2a) an observation that the variability of $\Delta^{33}\text{S}$ is largest in the oldest terrestrial rocks and becomes significantly smaller at approximately 2,400 Ma; (2b) an observation that the $\Delta^{33}\text{S}$ of proxies for seawater sulfate have risen from slightly negative values (~ -0.5 to -0.10‰) to generally positive values (0 to $+0.5\text{‰}$) over the past 2,000 million years; and (3) an observation that samples of Martian meteorites contain sulfate and sulfide that has variable and significantly negative $\Delta^{33}\text{S}$.

The Geologic Record of $\delta^{34}\text{S}$

Monster et al. (1979) and Cameron (1982, 1983) argued that the range of $\delta^{34}\text{S}$ observed in terrestrial rocks was small in the earliest parts of Earth's history (before $\sim 2,500$ – $2,700$ Ma) and became larger after this time. They argued that this general change in the observed variability of $\delta^{34}\text{S}$ reflects a response of sulfate-reducing bacteria to rising oceanic sulfate concentrations. They cited earlier studies of Harrison and Thode (1958) that documented a similar response in laboratory culture experiments and argued that rising sulfate concentrations was a global response to generally more oxidizing conditions for mineral weathering occurring at $\sim 2,500$ – $2,700$ Ma. The presence of one locality at North Pole, Western Australia

(~3,400 Ma), which was an exception to this general rule, exhibiting sulfides with significantly negative $\delta^{34}\text{S}$, has been argued to be evidence for the presence of ► [sulfate-reducing](#) and sulfur-disproportionating bacteria (bacteria capable of splitting one compound into two different compounds, in this case an electron donor and an electron acceptor) (Shen et al. 2001; Philippot et al. 2007).

Two observations made for later points in Earth history include an observation that the average values for $\delta^{34}\text{S}$ of sedimentary pyrite are generally near zero or slightly positive until about 550 Ma and that the variability for $\delta^{34}\text{S}$ increases from ~40‰ to ~60‰ starting around 800 Ma (Canfield and Teske 1996). The first observation may be attributable to a fundamental change in the way that sulfur is cycled within seafloor sediments and may reflect the initiation of significant bioturbation (displacement and mixing of sediment particles) that recycled sedimentary sulfur to seawater and allowed for the transfer of negative $\delta^{34}\text{S}$ to sedimentary pyrite (e.g., Canfield and Farquhar 2009). The cause of the amplification in the range of observed variability of $\delta^{34}\text{S}$ at ~800 Ma is debated but includes a variety of hypotheses related to changes in the ecology of the oceans and their impacts on sulfate concentration, bioturbation, and the cycling of sulfur by a more complex biosphere.

The Geologic Record of $\Delta^{33}\text{S}$

Farquhar et al. (2000) reported significant variability in the range of $\Delta^{33}\text{S}$ (correlated with $\Delta^{36}\text{S}$) of Archean and earliest Proterozoic rocks that disappeared at ~2,400 Ma. This variability was interpreted to reflect preservation of an imprint of atmospheric reactions that produce variations with nonzero $\Delta^{33}\text{S}$. This interpretation was based on the observation of nonzero $\Delta^{33}\text{S}$ in photolysis experiments, and in today's atmosphere, and a lack of plausible alternatives to produce similar isotope signals by liquid-phase or solid-phase reactions. The preservation of the $\Delta^{33}\text{S}$ signal in the rock record was inferred to reflect limited oxidative and reductive cycling of sulfur compared to that seen in the present-day sulfur cycle,

and this was linked to atmospheric oxygen levels and therefore carried implications for ► [oxygenation of Earth's atmosphere](#) and surface environments. Subsequent studies by Pavlov and Kasting (2002) presented arguments that the opening of pathways for the transfer of atmospheric signals to the surface also depends on oxygen levels and were consistent with this interpretation. An atmospheric origin associated with self-shielding (large optical depths that limit photodissociation of the most abundant isotope) rather than a primary photochemical origin for the effect has been proposed by Lyons (2009) but would not change the implications. Given the cross sections, some amount of self-shielding is inescapable, but whether it is the sole reason for the sulfur isotope effect remains to be demonstrated. Recently, it has been shown that other pathways associated with some thermochemical (liquid-phase) reactions exist for the production of anomalous $\Delta^{33}\text{S}$ (Watanabe et al. 2009). It is unclear at present whether this chemistry provides an alternative explanation for the early Earth record.

The $\Delta^{33}\text{S}$ of oceanic sulfate younger than 2,400 Ma deviates slightly from a value of zero as a result of the way biogeochemical reactions are linked within the sulfur cycle. Johnston et al. (2005) demonstrated that the $\Delta^{33}\text{S}$ of oceanic sulfate rose from slightly negative values (~ -0.5 to -0.10‰) to generally positive values (0–0.5‰) over the past 2,000 million years. This change was attributed to a transition from a sulfur cycle dominated by sulfate reduction to a sulfur cycle where the influence of sulfide oxidation and disproportionation was expressed. Recently Wu et al. (2010) have suggested that the $^{34}\text{S}/^{32}\text{S}$ and $^{33}\text{S}/^{32}\text{S}$ fractionations between seawater sulfate and buried pyrite may have changed approximately 300 Ma ago, suggesting a change in the oceanic cycling of sulfur that also may be linked to ocean ecology, bioturbation, and reoxidation pathways for biogenic sulfide.

Sulfur Isotope Records of Martian Meteorites

In the late 1970s and early to mid-1980s, a strong case was made that the SNC (shergottite, nakhlite,

and chassingite) meteorites came from Mars (Wood and Ashwal 1981; Bogard and Johnson 1983; Mccsween 1985, 1994). While these meteorites may not themselves constitute a fully representative suite of Martian rocks, their study provides a window into aspects of Mars science that is fundamental to our understanding of Mars. Farquhar et al. (2000, 2007) reported sulfate and sulfide from these meteorites with significant and variably negative $\Delta^{33}\text{S}$ and near-zero $\Delta^{36}\text{S}$. Variations of the magnitude seen in these meteorites are larger than that seen in other types of meteorites but are smaller than those seen in ancient terrestrial samples. The origin of this signal was interpreted to reflect isotope transformations on Mars that are related to atmospheric pathways for oxidation of sulfur to sulfate. These findings point to a significant role for these atmospheric pathways in the Martian sulfur cycle. They also call for an accounting of $\Delta^{33}\text{S}$ (and $\Delta^{36}\text{S}$) in future studies that seek to use sulfur isotopes as a tracer of possible biological processing of sulfur in the search for evidence of extraterrestrial metabolic activity.

Definition

The Sun is the central body of our solar system and the nearest star. It is a low-mass star of spectral type G2 V located on the main sequence in the Hertzsprung-Russell diagram, with an age of about 4.6 billion years. Its mass is 1.99×10^{30} kg and its bolometric luminosity amounts to 3.84×10^{26} W. The Sun shows diverse signs of magnetic activity, in particular sunspots, a warm chromosphere, a very hot magnetic corona, flares, coronal mass ejections, and the solar wind.

Overview

The Sun is a main-sequence star in the phase of core hydrogen burning, being in the midst of the longest stable phase of ► [stellar evolution](#) before the white dwarf phase. It is a metal-rich (population I) star with an age of approximately 4.6 billion years. It will spend another ≈ 5 Gyr before evolving off the main sequence. The Sun is classified as a low-mass star of spectral type G2. It entirely dominates the solar system in terms of mass and energy. Its luminosity is such that at the distance of the Earth, a total flux of 1366 W m^{-2} is measured (the ► [“solar constant”](#)). Some of the basic properties of the Sun are summarized in Table 1. Various appearances of the Sun and its environment are illustrated in Fig. 1.

This entry reviews our knowledge of the Sun and its environment with emphasis on features relevant for astrobiology. We therefore review the internal structure of the Sun including the magnetic

dynamo and nuclear fusion in a relatively cursory way, while more emphasis is put on the escaping radiation from the solar atmosphere. We specifically focus on radiation related to solar magnetic activity, including ultraviolet and X-ray radiation. This short-wavelength radiation is crucially important for ionization, heating, and chemical reactions in planetary atmospheres and therefore for the formation and evolution of life. Important questions related to the formation of life on Earth require knowledge of the solar constitution in earlier times of solar evolution. Systematic studies of stellar samples provide this information, which we will therefore address as well.

Sun (and Young Sun), Table 1 Basic parameters of the Sun

Stellar winds	Stellar winds
Mass	1.989×10^{30} kg
Radius	6.955×10^5 km
Average density	1.41×10^3 kg m ⁻³
Surface temperature	5770 K
Bolometric luminosity	3.846×10^{26} W
Spectral class	G2 V
Age	4.6×10^9 year
Sidereal rotation period	25.05 days (equator)–34.3 days (near poles)
Synodic rotation period	27.3 days at 16° latitude

Basic Methodology

The Sun is the only star that can be studied in spatial detail. This remains true even if a few stars have been marginally resolved by optical

Sun (and Young Sun), Fig. 1 Images of the Sun taken contemporaneously, showing the photosphere in the optical light (upper left), the corona in the extreme ultraviolet range (upper right), and an evolving coronal mass ejection seen in optical white light (lower images). interferometry, by speckle interferometry, or, as far as their magnetic atmospheres are concerned, by radio interferometry. But for no other star do we have similarly extensive methodology and diagnostics at hand as for the Sun.

Traditionally, radiation across the electromagnetic spectrum has been used to investigate all layers of the solar atmosphere. Specifically, the photospheric layers provide rich diagnostics in optical spectroscopy, including polarization diagnostics to infer strength and orientation of photospheric magnetic fields. The optically thin chromospheric and transition region layers with temperatures between 10^4 and 10^6 K reveal themselves best in ultraviolet emission lines. Million-degree coronal plasma emits in the extreme ultraviolet range and in X-rays, where again rich spectroscopic diagnostics are available to study temperature, density, and motion of coronal plasma. Nonthermal particles accelerated during flare episodes leave various traces at radio wavelengths and in hard X-rays and gamma rays. Although most of the electromagnetic spectrum is also studied routinely in solar-like stars (presently with the exception of nonthermal hard X-rays above 20 keV and gamma rays), the lack of spatial resolution has made solar studies indispensable for the interpretation of stellar atmospheres. In situ observations of high-energy particles (e.g., from flares), coronal mass ejections, and the solar wind are of course confined to our own solar system.

Although ground-based optical solar observatories can be used to study the solar photosphere and sunspots, investigations of higher layers in ultraviolet, EUV, and X-rays require space-borne instrumentation on satellites, such as the SOHO, Yohkoh, TRACE, STEREO, or the Solar Dynamics Observatory. The same is true for observations of high-energy particles in interplanetary space and also applies to highest-energy radiation such as hard X-rays and gamma rays during flares. In contrast, the highly diagnostic radio emission is easily observed in spectral and temporal detail with relatively modest-sized ground-based telescopes.

Our understanding of the solar interior has been revolutionized by helioseismology. Helioseismology is the analog of terrestrial

seismology although it probes sound waves in a gaseous environment. Convective motion in the outer layers of the solar interior excites acoustic waves, which develop standing waves. Sound waves traveling from the surface obliquely into the solar interior are refracted back to the surface owing to the increasing temperature toward larger depths and the temperature dependence of the sound velocity. Thousands of so-called pressure modes (p-modes) have been measured that together probe the internal structure in much detail except the central part of the Sun where nuclear reactions take place (there, sensitive measurements of g-modes would be required). Lower harmonics (p-mode waves with longer spatial scales) penetrate to deeper layers, while higher harmonics remain closer to the surface. Resulting oscillations of the photosphere can be recorded through Doppler shifts. The p-modes show a large spectrum of waves with an average period of 5 min. The observed oscillations can be inverted to derive the temperature and pressure profiles in the convection zone. Their detailed analysis provides much insight into the internal structure of the Sun.

Neutrinos define another important way to probe the solar interior, specifically the nuclear region. Detection of solar neutrinos has fundamentally confirmed the proton-proton chain reaction (p-p cycle; see below); although initially found to be deficient from the Sun, neutrinos oscillate between three flavors, the flavor produced in the Sun and initially detected in experiments being the electron neutrino. Considering this oscillation effect and measuring solar neutrinos of all flavors, there is no discrepancy between the standard solar model for the solar center and observations.

Magnetic fields play a major role in the solar atmosphere all the way from the photospheric layer to the corona and the solar wind. Photospheric magnetic fields are relatively easy to measure by making use of Zeeman splitting of spectral lines: magnetic fields split the atomic energy levels into sublevels, and the emitted radiation is polarized. Coronal magnetic fields can be deduced from approximate 3D extrapolations of photospheric fields based on some assumptions; alternatively, coherent radio emission diagnostics has been used to estimate field strengths in the emission region.

A key question relevant for the evolution of life refers to the long-term evolution of the Sun, its magnetic activity, and radiation spectrum. Although theoretical models of stellar evolution provide deep insight into the evolution of basic parameters (radius, surface effective temperature, etc.), the generation of magnetic activity and the solar wind is not sufficiently well understood to be modeled on evolutionary timescales. Here, stellar samples of solar analogs with known ages are used, with the goal of finding systematic trends with age.

Key Research Findings

The Sun's Internal Structure, Energy Production, and Composition

Our knowledge of the Sun's internal structure and physical state is summarized in the so-called standard model that calculates temperature, pressure,

and density as a function of radius, fulfilling the conservation equations and the boundary conditions at the solar surface.

The central region of the Sun (within a radius of approximately 10^5 km – see Fig. 2) is characterized by temperatures of about 16×10^6 K and a density of 1.5×10^5 kg m⁻³. In this core region, helium (⁴He) is synthesized from hydrogen (p) nuclei mainly in the proton-proton chain reaction:

where γ stands for energy emitted in a photon and ν_e is an electron neutrino. There is also a second path to ⁴He involving ⁷Be, ⁷Li, and ⁸Be, and a small percentage of the energy is produced in the

Sun (and Young Sun), Fig. 2 Schematic cross section of the Sun and sketch of features in the solar atmosphere. (Credit: NASA/HEASARC)

so-called CNO cycle. Within the inner $\approx 71\%$ of the solar radius, the energy liberated from the central fusion process is transported radiatively. Outside this region, convection plays a dominant role up to the solar photosphere.

The Sun is composed predominantly of hydrogen (approximately 70% by mass or 91% by number of atoms) and helium (28% by mass or 9% by atom number); heavy elements, predominantly carbon, nitrogen, oxygen, neon, magnesium, silicon, sulfur, and iron, contribute the remaining 2% of the mass. The exact composition is still a matter of debate but plays an important role for the plasma opacity and therefore the radiative transport in the solar interior and the depth where energy transport becomes dominated by convective motions.

The Solar Photosphere and Sunspots

The visible surface of the Sun defines the photosphere, that is, the layer from which photons in the visible range of the electromagnetic spectrum freely escape. This layer is only a few 100 km thick and separates the solar interior from the outer atmosphere. Its spectrum can be approximated by a blackbody spectrum corresponding to a temperature of about 5770 K. This spectrum defines most of the solar irradiance (Fig. 3), although important contributions are added at

short wavelengths as a consequence of magnetic activity.

The photosphere reflects the underlying convective motions at several scales, showing granulation structure on length scales of 100–1000 km, mesogranulation on scales of 5000–10,000 km, and supergranulation on scales of about 15,000–20,000 km. In individual granules, hot, subphotospheric gas flows up in the center, radiates and cools, and then flows down in the intergranular lanes. In the latter places, bright points related to magnetic flux tubes are concentrated. Concentrations of magnetic flux tubes at the supergranulation boundary form a magnetic network visible also in the overlying chromosphere.

The photosphere hosts the remarkable sunspots. These are regions in which strongly bundled, vertical magnetic fields with a field strength of about 0.2–0.3 T suppress convection and therefore impede the energy flow from below; their temperature is therefore lower, reaching typical values of 4500 K. The sunspot core region, the umbra, is surrounded by the radially structured penumbra, which is permeated by inclined magnetic fields, and spot groups may further be surrounded by larger areas containing strong, vertical magnetic flux tubes appearing brighter than the surrounding photosphere. These latter regions,

Sun (and Young Sun),

the faculae, make up for the deficit of radiation from the sunspots, such that the net brightness at times of large sunspot coverage is slightly higher than at times of small coverage; the “solar constant” therefore cyclically varies by a small amount in concert with the solar spot cycle (see below), being higher by about 0.1% during the spot or activity maximum.

Spots appear in pairs with opposite magnetic polarity. The polarity of the spot leading in heliographic longitude is constant for one (north or south) hemisphere for a given 11-year sunspot cycle, which is an important observation that has helped formulate a dynamo theory for the Sun.

Magnetic flux tubes are also present in regions outside sunspots. Such magnetic flux elements are concentrated in intergranular lanes, where magnetic flux concentrations with kilogauss field strengths and sizes of less than 100 km are inferred. Despite their small size, their large number contributes significantly to the total solar magnetic flux.

The Solar Chromosphere

The chromosphere is a “layer” of tenuous gas above the photosphere, ranging in temperature from the temperature minimum at the top of the photosphere to about 20,000 K where it merges with the chromosphere-corona transition region. In modern concepts, the chromosphere is a complex mixture of cool and hot magnetically structured inhomogeneities subject to many forms of variability (flares, explosive events, flows, prominences, etc.). It is on average only about 2000 km thick, but is a source of important ultraviolet emission, in particular in prominent line transitions such as Balmer lines and lines of Ca II and He I (using the standard astronomical notation of I for neutral atom, II for once ionized, etc.). Larger heights (of order 10,000 km) are reached by the jetlike hot spicules rising into the lower corona with velocities of a few tens of kilometers per second.

The chromosphere forms a dynamic network corresponding to the photospheric supergranule cells. Nearly vertical magnetic fields emerging from the photosphere in these regions rapidly fan out, forming a canopy in the upper chromosphere that seems to overlay cool, weak-field, CO-rich

gas in the lower chromosphere. The canopy region itself is the anchorage region of the overlying coronal loops. The chromosphere is particularly well expressed in magnetic active regions. Around sunspots, the chromosphere is bright, defining the chromospheric plage (a continuation of the photospheric faculae). The heating of the chromospheric gas is not yet fully understood, but may involve dissipation of acoustic waves in shocks, magnetodynamic waves, or magnetic reconnection (e.g., in bright points).

Extensions of chromospheric material into the corona are seen in many large-scale filaments or prominences made of cool gas suspended by magnetic fields at coronal heights. They may reside there for weeks or months, but may also be activated and ejected, accompanied by flares or coronal mass ejections.

The Solar Transition Region

The temperature rises very rapidly above the chromosphere on length scales of only a few hundred kilometers, from 2×10^4 to 10^6 K. This chromosphere-corona transition region (TR) is a very inhomogeneous and dynamic layer, featuring flows (mostly downflows with velocities of up to 20 km s^{-1}), flares, and short explosive events involving velocities of 100 km s^{-1} ; many of these processes connect to the overlying, strongly variable corona. Various physical parameters change fundamentally across the TR; helium changes from the partially ionized (below) to the fully ionized state (above), dramatically reducing the radiative losses and producing a rapid jump of the temperature to the adjacent corona. Below the TR, the plasma thermal pressure dominates plasma motion, dragging magnetic fields with it, while above the TR, the magnetic pressure dominates, such that plasma is dragged by the magnetic fields. Much of the TR is structured in magnetic loops connecting footpoints of different polarity. The TR can best be observed in emission lines at wavelengths below 200 nm (e.g., He II, C IV, O VI).

The Solar Corona

The outermost and hottest region of the solar atmosphere is the magnetically structured corona.

Although the corona is well known from solar eclipses when photospheric light scattered by free electrons and dust reveals its large-scale magnetic structure, it is really a phenomenon rooted in high-energy processes in the tenuous, extended magnetic fields that are anchored in the photosphere. The corona is best observed in the extreme ultraviolet (EUV) and X-ray ranges where the hot plasma confined by closed magnetic fields emits most of its radiation or in the radio range where high-energy, accelerated electrons emit various kinds of radiation such as gyrosynchrotron radiation and a plethora of coherent radiation types. The solar coronal temperature of a few million degrees has defined one of the most persistent riddles in astronomy: among the favored theoretical concepts to explain coronal heating figures magnetic reconnection in flares, in particular also in the large number of microflares or nanoflares occurring ubiquitously across the corona.

The coronal magnetic fields structure the plasma into large active regions overlying magnetic sunspot groups (Fig. 4); such volumes are filled with coronal loops with both footpoint regions anchored in the chromosphere. They

range from small bright points, probably simple magnetic loops above the chromospheric layer, to large-scale arcades connecting regions of opposite polarity on the solar surface. Coronal streamers may be attached to these structures, pointing outward into the solar wind region to distances of order one solar radius (Figs. 1 and 5).

Coronal active regions display a high level of variability, including flares, mass flows, and coronal mass ejections. Intermittent heating, changing magnetic connectivity in reconnection events, and magnetic instabilities define the corona as an extremely dynamic region. Various types of oscillations of magnetic coronal loops have been measured with periods in the range of seconds to minutes; propagating magnetohydrodynamic waves have been detected in the EUV range, including global waves expanding from strong flare sites.

Large volumes of the corona are not directly connected to the underlying photospheric and chromospheric active regions, but they reveal similar magnetically closed structures such as transequatorial loops or X-ray bright points and similar dynamic phenomena as in active regions,

Sun (and Young Sun), Fig. 4 Three images of the solar atmosphere taken at the same time but in different wavelength regions. such as magnetic reconnection, mass flows, and nanoflares. These regions have traditionally been called “quiet-Sun regions” although absence of variability and dynamic phenomena are no longer implied by this term.

A physically distinct type of coronal feature emerges in regions dominated by nearly radial, “open” magnetic fields; these “coronal holes” contribute importantly to the fast solar wind but appear as very dim regions in X-ray or EUV images, as a consequence of their low densities. Prominent coronal holes are often seen in the polar regions of the Sun.

Solar Rotation, the Solar Magnetic Dynamo, and Magnetic Cycles

The Sun’s rotation period, P , is a function of depth and latitude. The surface rotation period varies between about 25 days at the equator and about 36 days near the poles, characterizing solar differential rotation. Throughout the convective zone, the rotation period determined using helioseismology methods depends on latitude in a similar way as on the surface. In contrast, the core shows approximately solid-body rotation.

The interaction between differential rotation and convection generates an internal dynamo at the base of the convection zone, in the so-called tachocline where the rapid change in rotation together with convection is held responsible for the amplification of magnetic fields. The shearing differential rotation generates toroidal fields from poloidal fields. These fields eventually rise buoyantly to the surface in the form of magnetic flux tubes; there, they become evident in a plethora of features related to magnetic activity such as bipolar sunspots and coronal magnetic loops.

There is as of yet no complete theory that explains all features of the solar magnetic dynamo. At the beginning of a magnetic cycle, spots appear at relatively high heliographic latitudes (about 35° on both hemispheres), but the regions of spot emergence slowly migrate toward the equator in the course of the 11-year sunspot cycle. A new spot cycle starts when new field concentrations appear at high latitudes. Their polarity (leading vs. trailing spot) is reversed for a given hemisphere during the new cycle, thus

defining the 22-year magnetic (or Hale) cycle of the Sun.

Spot and magnetic cycles are not only evident in sunspots but can be monitored in essentially all tracers of magnetic activity, including coronal X-ray emission, the rate of flares, prominences, mass ejections, or the structure of the solar wind. The same features are used as diagnostics of solar magnetic activity, that is, the complex interplay between magnetic fields that leads to time-variable energy release, heating, acceleration, and mass motions.

Active Regions, Flares, and Coronal Mass Ejections

Active regions on the Sun are areas of enhanced magnetic flux, that is, regions where magnetic flux tubes break through the photosphere from the interior, in pairs of opposite polarity. Active regions can therefore be traced throughout all layers of the solar atmosphere, showing up, in larger examples, as sunspot groups and faculae in the photosphere, spots and chromospheric plages at chromospheric levels, and large magnetic loop systems at transition region and coronal heights. These regions are particularly prone to instabilities leading to large-scale magnetic energy release and reconnection in flares and coronal mass ejections.

Observationally, solar flares express themselves as sudden increases in electromagnetic radiation, localized in solar active regions or coronal loops in which obviously a large amount of energy is liberated following some instability. Flares may last from minutes to several hours. Flares are currently considered to be a consequence of magnetic reconnection in non-potential (mostly coronal) magnetic fields. Non-potential fields emerge in the corona as a result of convective motions of the photospheric/chromospheric footpoints of magnetic loops. Increasingly stressed fields occasionally adjust by changing their topology, settling in a lower-energy state by liberating energy from the non-potential field. This large-scale reconnection process is induced by field annihilation once antiparallel field components (e.g., from different coronal loops) are pushed together in the corona. In the course of

this process, particles are accelerated to high energies, plasma can be heated locally, and plasma jets can be ejected. Initially “open” magnetic fields may reconnect in such a way as to produce systems of closed magnetic loops, while overlying magnetic regions may “detach” and be ejected from the corona, escaping into the interplanetary space as “coronal mass ejections” (CMEs; Fig. 5), accompanied by an erupting prominence.

The size of CMEs may rapidly evolve to the order of a solar radius while they escape with a speed of 10^2 – 10^3 km s⁻¹. At 1 AU, a CME evolves to a typical size of 0.2 AU. It may carry of order 10^{15} – 10^{16} g of material into the solar wind.

The relation between CMEs and classical flares is still a matter of debate as there is no one-to-one correlation between these expressions of magnetic energy release. Flares and coronal mass ejections may simply be two observational manifestations

of large-scale coronal magnetic energy release by the reconnection process.

A large fraction of the released flare energy appears in the form of kinetic energy of highly accelerated electrons and ions. As they propagate along magnetic fields, they eventually encounter denser TR and chromospheric gas layers where they collide. The collisions result in nonthermal hard X-ray and gamma-ray radiation during the first minutes of a flare event, also known as the impulsive phase. The bulk part of the particle energy is, however, deposited as thermal energy in the chromospheric plasma, signatures of which are strong ultraviolet and optical enhancements in the magnetic footpoint regions. Electron temperatures up to about 20 million degrees are reached in the collision zone, which, as a consequence of the corresponding pressure increase, expands upward along the closed magnetic-field lines to fill coronal loops (chromospheric evaporation). This is the gradual phase of the flare when strong X-ray emission from coronal loops dominates the radiative losses. Various kinds of radio emission from the accelerated electrons (e.g., gyrosynchrotron emission from electrons spiraling around magnetic fields) or electron populations with non-Maxwellian velocity distributions can be monitored during large portions of a solar flare. Radio emission is, together with hard X-rays and gamma rays, an ideal tracer of the energy release and particle acceleration processes. Similarly, radiation in Balmer lines from chromospheric heights is prominent during extended periods of a flare. Flares are also the source of high-energy particles (protons, electrons, ions) ejected from the Sun and traveling in interplanetary space. Chromospheric filaments or prominences can be activated and ejected in the course of a flare or a coronal mass ejection.

Flares may be important contributors to the coronal heating process because they occur stochastically and in large numbers at many places in the solar corona. The distribution of their occurrence rate as a function of released energy shows a dramatic increase toward low-energy (small) events. The cumulative energy of such “micro-” or “nano-” flares could be sufficient to heat the

Sun (and Young Sun), Fig. 5 A coronal mass ejection (*lower left*) seen by the LASCO (Large Angle and Spectrometric Coronagraph Experiment) instrument on the SOHO satellite. Several coronal streamers (e.g., *upper right*) can also be seen. The solar disk was recorded by the EIT (Extreme ultraviolet Imaging Telescope) instrument and shows hot coronal structures. (Credit: SOHO/EIT and LASCO Consortia; SOHO is a mission of international cooperation between ESA and NASA).

entire coronal gas, although current debate has not converged to a clear answer.

Flares and mass ejections lead to significant interactions with planetary environments. Flare X-ray radiation increases the ionization of upper planetary atmospheres dramatically. When CMEs reach the Earth, they may interact globally with the magnetosphere and induce geomagnetic storms. Together with the solar wind, they interact with the higher atmosphere, carrying away ions and neutrals and thus contributing to atmospheric erosion.

Solar Wind

The Sun continuously loses mass in an approximately radially expanding solar wind. It consists of hot ($\approx 10^5 - 10^6$ K) plasma. The wind is permeated and structured by magnetic fields originating in the solar photosphere and also by shocks, waves, and turbulence. It is therefore a highly variable structure filling the interplanetary space and interacting with planetary magnetospheres and atmospheres, leading to the removal of atoms and ions in the higher atmospheres and therefore to planetary erosion. High-energy particles (from the Sun, planetary bow shocks, and cosmic rays) and coronal mass ejections are also occasionally immersed in the solar wind.

The solar wind is a consequence of the high coronal temperatures close to the Sun, leading to coronal expansion rather than a hydrostatic structure. The processes of wind heating and acceleration are, however, still poorly understood and may involve wave dissipation and magnetic reconnection. The present-day average mass loss of the Sun in the magnetized wind is approximately $2 \times 10^{-14} M_{\odot} \text{ year}^{-1}$. The wind flow varies locally depending on whether it originates in magnetic streamer regions above the magnetically closed coronal active regions, leading to the slow wind with velocities of $300\text{--}500 \text{ km s}^{-1}$, or in open-field coronal holes, leading to the fast wind with velocities of approximately $600\text{--}800 \text{ km s}^{-1}$. This structure is further modulated by the solar activity cycle.

The volume filled by the solar wind defines the heliosphere. At distances beyond 90 AU, the solar wind collides with the interstellar medium,

forming a termination shock, a heliopause, and the bow shock beyond which the undisturbed interstellar gas is encountered. Because the Sun moves relative to the interstellar plasma, the heliosphere is compressed in the direction of solar motion and elongated in the opposite direction.

The Sun in Time

The past magnetic evolution of the Sun is studied using solar analogs with different ages and therefore activity levels. For stars with masses $\leq 1.5 M_{\odot}$ and ages of at least a few hundred million years, angular momentum loss by a stellar wind brakes rotation in such a way that rotation becomes nearly uniquely determined by the stellar age. Age thus becomes the only independent variable on which the rotation period and, through the internal magnetic dynamo, magnetic activity at all levels of the stellar atmosphere depend, probably also including characteristics of the stellar wind. Studying a sample of near-solar-mass stars with known ages back to stages close to the zero-age main sequence (ZAMS), age is, therefore, sufficient to approximately reconstruct the history of our Sun and the interaction of its magnetic activity with its environment.

The Evolution of the Solar Wind

Stellar equivalents of the solar wind have not yet been detected; judged from the presence of coronae in all main-sequence solar analogs, coronal winds are undoubtedly present in these stars as well. The evolutionary spin down of cool stars like the Sun is in fact the best – albeit indirect – proof of the presence of ionized, magnetized winds because such winds carry away angular momentum from the star.

Ionized [stellar winds](#) are, in principle, sources of thermal bremsstrahlung in the radio regime, but the emission is too weak to be detected even in the nearest stars with current technology. A presently more promising approach makes use of Lyman-alpha ($\text{Ly}\alpha$) absorption in the so-called astrospheres, stellar analogs to the solar heliosphere. The astrospheres are permeated by neutral hydrogen with $T \approx (2\text{--}4) \times 10^4$ K. Much of this gas is piled up between the “heliopause” and the bow shock, forming a “hydrogen wall”

that can be detected through excess absorption of the Ly α line. The measured absorption depths are then compared with results from hydrodynamic model calculations. It is found that the astrospheric absorption should scale with the wind ram pressure, which itself scales with the mass-loss rate assuming that the wind velocity is constant. A systematic observational study shows that dM_w/dt correlates with the stellar X-ray luminosity (L_X) and with stellar age (t),

$$dM_w/dt \propto L_X^{1.34 \pm 0.18}$$

and equivalently,

$$dM_w/dt \propto t^{-2.33 \pm 0.55}$$

The stellar-wind mass loss can therefore – in principle – be used as a genuine activity indicator. The mass loss is thus expected to be higher in young, magnetically active stars. Extrapolating the above law up to stars at the saturation limit (with an average surface magnetic flux of $2 \times 10^6 \text{ erg cm}^{-2} \text{ s}^{-1}$) suggests dM_w/dt of the youngest solar analogs to be about a thousand times higher than the present-day solar mass loss ($dM_w/dt \approx 2 \times 10^{-14} M_\odot \text{ year}^{-1}$). The above power-law relations appear to break down for the most active stars, however. While intermediately active stars may reach mass-loss rates two orders of magnitude higher than the Sun, the most active, youngest main-sequence stars suggest loss rates no more than about ten times the present solar value. The cause for this breakdown has not been identified but could be related to the appearance of high-latitude active regions (spots) in the most active stars; if the magnetic field becomes more akin to a global dipole, then wind escape may be inhibited in such stars.

The Rotation Rate of the Young Sun

Because the magnetized stellar winds transport angular momentum away from the star, a solar analog spins down with age. The rate of change of angular momentum is related to the mass-loss rate, the rotation rate, and the Alfvén radius. For solar analogs, the rotation period is

$$P = 0.21 t_6^{0.57} [\text{d}]$$

where t_6 is the age in Myr after arrival on the ZAMS and d means day. This equation implies an increase in rotation period from ZAMS age to the end of the main-sequence life by a factor of about 20.

For solar analog stars with ages of less than a few hundred million years, the [stellar rotation](#) period is not a function of age but of the pre-main-sequence history, especially the history of circumstellar-disk dispersal. Once the inner disk disappears, the lack of magnetic locking via star-disk magnetic fields and the contraction of the star toward the main sequence will spin up the star and thus determine the initial rotation period on the ZAMS. After arrival on the main sequence, the angular momentum loss in a wind will decrease the magnetic activity and presumably also the wind mass loss itself; therefore, the rotation period will eventually converge to a value that is only a function of age, as specified above.

The Evolution of the Solar Magnetic Field

Polarization measurements of the integral light from solar analog stars have provided important information on the average field strength of magnetic areas on the star, including corresponding surface filling factors. Doppler imaging methods have further deepened our understanding of the size, distribution, location, and evolution of stellar magnetic fields.

Whereas maximum magnetic-field strengths in younger solar analogs are similar to the present-day Sun, the filling factors of magnetic active regions are much higher; spot coverage of order 10% is common and testifies to much increased magnetic activity in the young Sun. This obviously relates to an enhanced dynamo as a result of the increased rotation rate of young solar analogs.

Although surface spot distributions vary significantly between young solar analogs, most stars show evidence of high-latitude magnetic activity and the presence of polar spots. The origin of polar magnetic activity has been related to strong Coriolis forces acting on magnetic flux bundles

that rise from the dynamo region of the star. This force would deflect rising flux to higher altitudes. Alternative models use magnetic bipoles (structures with two footpoints of opposite polarities) injected at various heliocentric latitudes and migrating along meridional flows. A high injection rate of interacting bipoles leads to the formation of nested polar rings of opposite polarity.

The Evolution of Solar Activity and High-Energy Radiation

Stellar evolution calculations indicate that the young, zero-age main-sequence Sun was bolometrically about 30% *fainter* than at present. This trend is related to the fact that hydrogen is slowly being converted into helium in its core, raising the density and causing corresponding increases in temperature and the rate of nuclear fusion.

This slow, evolutionary increase in optical luminosity of the Sun contrasts sharply with all radiation that is related to magnetic activity. Meteoritic evidence indicates that the Sun was magnetically much more active in its youth than at present. This direct evidence is fundamentally supported by observations of young solar analogs that show systematically higher levels of magnetic activity and related electromagnetic radiation.

The cause of this steady decline of magnetic activity during the main-sequence evolution is, as already mentioned above, the declining dynamo as a star spins down by losing angular momentum through its magnetized wind. Because magnetic activity is particularly important for the generation of short-wavelength radiation (ultraviolet emission from the chromosphere and the TR; EUV and X-rays from the TR and the corona), this part of the spectrum shows particularly strong evolutionary trends; the short-wavelength input into planetary atmospheres thus diminished significantly with time.

The young Sun showed stronger rotationally induced modulation in the optical light due to surface magnetic spots but also due to magnetic activity cycles that induced light variations up to 0.3 magnitudes in the course of spot cycles; such cycles have been found in solar-like stars, with cycle periods ranging from 2 to 13 years. The presence of excess emission from photospheric

faculae outweighs the darkening by the spot area in old solar analogs, making these stars slightly brighter in optical light during activity maxima, while in young stars, spots dominate and make them fainter. Cycles are not present in all solar-like stars, however, and irregular variations abound among very active examples.

The increased magnetic activity in younger solar analogs enhances ultraviolet emission from transition regions by factors of a few, in particular in emission lines forming at temperatures around 10^5 K. Much more dramatic changes must have occurred in the evolution of the shorter-wavelength radiation from the solar corona (Fig. 6). Studies of solar analogs with ages of tens to about hundred million years in young stellar clusters and in the field indicate X-ray and EUV luminosities exceeding the present-day solar output by several hundred to approximately thousand times. The same is true for stars in the younger, pre-main-sequence T-Tauri phase.

This enhanced radiation is a consequence of higher-density coronal plasma combined with a much larger filling factor of magnetic active regions. Also, the characteristic temperature of young coronae is higher, reaching average levels of 10–20 million K (Sun: two million K), and therefore the X-ray emission is much harder than X-rays from the present-day solar corona. How the corona can be kept three orders of magnitude more energetic and ten times hotter than the present-day solar corona is unclear; an interesting possibility is excess heating by a high rate of flares. Such “continuously flaring coronae” may be important as they also produce appreciable levels of gamma rays and high-energy particles that interact with planetary atmospheres.

The decaying trends of the short-wavelength radiation are well fitted by power laws that become *steeper toward shorter wavelengths*, as summarized in Table 2. A power-law decay law has been assumed for the rotation rate with age t , $\Omega \propto t^{-0.6 \pm 0.1}$. Table 3 provides numerical estimates for the solar spectral irradiance at various ages.

X-ray radiation thus suffered by far the strongest reduction (by three orders of magnitude) in the course of the Sun’s history, initially achieving

Sun (and Young Sun),

Fig. 6 Solar irradiance in the ultraviolet, extreme ultraviolet, and X-ray ranges for various ages of the Sun as derived from observations of solar analogs. The irradiance refers to a distance of 1 AU from the Sun in the absence of a planetary atmosphere. Stellar names and ages are given in the middle of the figure (where radiation is absorbed by the interstellar gas). (Reproduced by permission of ASP)

Sun (and Young Sun), Table 2 Long-term trends of short-wavelength solar radiation

Radiation type	Symbol	Relation with rotation	Relation with age
UV line radiation from chromosphere	L(chrom)	$\propto P^{-1.25 \pm 0.15}$	$\propto t^{-0.75 \pm 0.1}$
UV line radiation from transition region	L(TR,UV)	$\propto P^{-1.6 \pm 0.15}$	$\propto t^{-1.0 \pm 0.1}$
FUV from transition region (920–1180 Å)	L(TR,FUV)	$\propto P^{-1.4}$	$\propto t^{-0.85}$
EUV/X-rays from corona (20–360 Å)	L(EUV)	$\propto P^{-2.0}$	$\propto t^{-1.2}$
X-rays from corona (1–20 Å)	L _X	$\propto P^{-3.2}$	$\propto t^{-1.9}$

as much as 0.1% of the bolometric output or $(2-4) \times 10^{30} \text{ erg s}^{-1}$. The trends are graphically illustrated in Fig. 7.

Applications

At its ZAMS stage, the Sun's luminosity was only 70% of its present-day level. In the absence of an atmosphere, the Earth's surface equilibrium temperature would then have amounted to 255 K. Assuming an albedo and an atmospheric composition equal to values of the present-day Earth, the mean surface temperature would have been below the freezing point of seawater until ≈ 2 Gyr ago. The increase of the surface temperature in the presence of an atmosphere is due to the greenhouse effect. The present-day atmosphere of the Earth raises the surface temperature by only 33 K compared to the atmosphere-free equilibrium value. Evidence for a mild early climate both on the Earth and Mars (the [Faint Young Sun Paradox](#), FYSP) either requires substantially more effective greenhouse mechanisms from the presence of larger amounts of, for example, CO_2 or methane or a lower albedo (see [Faint Young Sun Paradox](#)).

Increased wind mass-loss rates may solve the FYSP as well. The Sun itself may have been more luminous in its past, which would imply that it had a higher mass by a few percent, having lost the extra mass by the solar wind and CMEs. However, estimates of the total wind mass loss seem to be insufficient to support this model (see [Faint Young Sun Paradox](#)).

The ionized and magnetized solar wind interacts strongly with planetary magnetospheres and atmospheres. Wind-planet interactions have played an important role in the formation and evolution of planetary atmospheres and consequently the formation of life on Earth. Irradiation of upper atmospheric layers by high-energy (EUV, X-ray) photons leads to atmospheric heating in the thermosphere and eventually to thermal escape from the exosphere above the thermosphere. In the exosphere, the mean free path of the particles is large; particles, in particular hydrogen atoms, with thermal energies exceeding the gravitational binding energy escape into space (Jeans escape). If in the upper atmosphere the mean particle energy exceeds the gravitational binding energy ($kT > mv_{\text{esc}}^2/2$, where v_{esc} is the escape velocity), then the exosphere becomes unstable and escapes ("blows off") into space.

Evaporation played an important role in early Venus. If surface water was initially present in large quantities, it would have evaporated due to a more efficient greenhouse (Ingersoll 1969; Kasting 1988) and subsequently dissociated in the high atmosphere due to strong solar EUV irradiation (Kasting and Pollack 1983) after which hydrogen atoms escaped to space. Hydrodynamic escape conditions for hydrogen applied as long as 250 Myr after the Sun's arrival on the main sequence; a terrestrial water ocean could have escaped in as little as 50 Myr from Venus (Kulikov et al. 2007).

For the young Mars, there is clear evidence for a warmer climate and liquid surface water. Evidently, a strong greenhouse would be required, but its origin is debated (Chassefière and Leblanc 2004). Hydrodynamic escape conditions may have applied to Mars during the first few hundred million years for hydrogen (Kulikov et al. 2007) and possibly for heavier gases such as C, N, and O as well (Tian et al. 2009).

Atmospheric escape is also driven by the interaction of high-energy (nonthermal) particles and the solar wind; here, the escape process is related to microscopic, nonthermal mechanisms, in particular dissociative recombination or photochemical escape (in which the forming neutrals are energetic), ion pickup (in which ions produced by photons or particle irradiations are dragged along by magnetic fields), ionospheric outflow, and ion sputtering (in which newly produced atmospheric ions re-impact and eject neutral particles; see, e.g., Chassefière and Leblanc 2004; Kulikov et al. 2007; Lundin et al. 2007). These processes are thought to have fundamentally altered the atmospheres of Venus, Earth, and Mars, leading to strong loss of oxygen (Lammer et al. 2006) and therefore water after its photodissociation in the upper atmosphere. The amount of shielding depends on the strength of the wind and its ability to compress the magnetosphere. A strong magnetosphere around the Earth, shielding the lower atmospheric layers, may have been instrumental in retaining much of its water and making it habitable.

In the case of the young Venus, oxygen could have been lost from the atmosphere as a consequence of ion pickup by the solar wind in a matter

of tens of million years (Lammer et al. 2006; Chassefière 1997), but a very strong solar wind – perhaps stronger than inferred indirectly for the young Sun – would have been required. A similar process as well as sputtering may have applied to the young atmosphere of Mars. But for Mars, the lack of a magnetic shield already early on in its evolution further strengthened interactions between the strong solar wind and the upper atmosphere, and escape processes were additionally enhanced by the weak gravitational potential of Mars. Some calculations indicate that a global Martian ocean of 12–15-m depth may have been lost as a consequence of such processes (Lammer et al. 2003; Chassefière and Leblanc 2004).

Coronal mass ejections (CME) add significantly to atmospheric erosion. An ejection rate of several CMEs per day acts like an enhanced solar wind and will therefore further compress planetary magnetospheres and erode the upper atmospheres (Khodachenko et al. 2007), especially in combination with enhanced exospheric heating by EUV irradiation and its consequent exospheric expansion (Lammer et al. 2007).

The future Sun will continue to affect planetary atmospheres and therefore habitability significantly, albeit in a progressively different way. As the solar bolometric output will gradually increase during the next 5 Gyr, the surface temperatures of the planets will increase. For the Earth, an increase by 60–70 K was predicted (Sagan and Mullen 1972). Beyond that phase, Sun-planet interactions will start changing fundamentally as the Sun will develop toward its giant phase. Then, it will expand considerably although its surface temperature will drop; at the same time, a strong solar wind mass loss will set in, but at that time the habitable phase of the Earth will be long gone. Eventually, a planetary nebula will be ejected from the Sun, expanding across the solar system and beyond.

Future Directions

Solar physics is an extremely rich field, involving the study of the solar interior, magnetic-field generation in a dynamo, plasma physical processes in the outer atmosphere, and various processes of particle acceleration and heating. Some of the

most pressing issues in solar physics and related stellar astronomy are listed below:

- The precise solar composition in terms of chemical elements, which is of fundamental importance to test the standard model of the solar interior.
- A comprehensive theory of solar magnetic-field generation in the internal dynamo.
- The problem(s) of chromospheric and coronal heating by waves and/or magnetic processes, possibly involving microflares and nanoflares.
- The acceleration and heating of the solar wind.
- Direct detection of ionized stellar winds based on radio emission.
- Improved modeling of interactions between the solar wind or solar radiation and young planetary atmospheres.

Super-Earths

Nader Haghighipour

Institute for Astronomy, University of Hawaii-
Manoa, Honolulu, HI, USA

Exoplanets · Mini-Neptunes · Transit · Kepler
space telescope

Definition

Super-Earth is the suggested term for a diverse class of planets with masses ranging from two to ten Earth masses. Prior to the operation of the *Kepler* space telescope, the value of the minimum mass of a planet was used to define the term “super-Earth.” After the detection of many small planets by the *Kepler* telescope, in the interest of identifying small, rocky planets that could be habitable, in addition to mass, a radius criterion was also added to the definition. A “super-Earth” is, therefore, a planet with a mass of two to ten Earth masses and radius of 1–1.8 Earth radii.

Overview

The first super-Earth around a main sequence star was discovered by Rivera et al. (2005) using the radial velocity technique. (Note that in 1992, Wolszczan and Frail (1992) discovered at least two terrestrial-sized planets around the pulsar PSR 1257+12. See the entry on “► [Pulsar Planets](#).”) Thanks to several ground- and space-based observational projects, to date, the number of these objects has exceeded 900. One major outcome of the *Kepler* satellite survey has been to show that super-Earths are very common and its population is now better characterized. In particular, Fulton et al. (2017) showed that using high-resolution spectroscopy to obtain more precise stellar properties, the population of super-Earth could be differentiated from the population of mini-Neptunes (see Fig. 1). Later, improving the stellar parameters using the precise astrometry allowed by the satellite *Gaia* allowed to constrain the two populations even better (Fulton et al. 2018). More details can be found in the entry “► [Transiting Planets](#).”

For the past few years, the formation and characteristics of super-Earths have been the subject of extensive research. This is primarily because being slightly larger than a typical terrestrial planet, these

Super-Earths,

Fig. 1 Radius distribution of the super-Earths and mini-Neptune planets. (Figure adapted from Fulton et al. (2017)). The peak on the right corresponds to the mini-Neptune family: planets which are thought to be dominated by a thick hydrogen and helium atmosphere, the left peak corresponds to the population of super-Earths, that is, planets with a higher density, which could be predominantly rocky

objects can have a solid surface with a solid-to-gas or liquid-to-gas phase transition at their upper boundary, similar to Earth. Super-Earths have the capability of developing moderate atmospheres and may have dynamic interiors with plate tectonics – two conditions that would render a super-Earth potentially habitable if its orbit were in the habitable zone of its host star.

Unlike Earth-sized planets, super-Earths are relatively easy to detect. Current observations of super-Earths have indicated that these objects seem to be more common around cool and low-mass stars (e.g., Dressing and Charbonneau 2013; Swift et al. 2013), where the habitable zone is in closer orbit. Two prime examples of such systems are Gliese 581, an M3V star with one or two potentially habitable super-Earths, and the M1.5 star GJ 667C, with up to three super-Earths in its habitable zone including the 4.5 Earth-mass planet GJ 667Cc. A recent example, which has stirred the community, is K2-18, an eight Earth-mass planet in the Habitable Zone of its M2.5 dwarf star. Using the Hubble Space Telescope, several teams managed to detect water vapor and clouds in its atmosphere (Benneke et al. 2019; Tsiaras et al. 2019). However, K2-18 with a radius of about 2.6 Earth radius is more likely to be a mini-Neptune than a super-Earth. Nonetheless, this observation shows that atmospheric characterization is improving toward the detection of important atmospheric species around smaller and smaller planets, which is a necessary step to 1 day detect life.

Supercontinent

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

A supercontinent is a landmass comprising a large fraction of the entire continental crust. It is the product of the assembly of many smaller

continents into one single continent. Supercontinents form in cycles (e.g., Mitchell et al. 2021), coming together and breaking apart about every 300–500 million years as a result of the plate-tectonic movements (Wilson's cycle). Pangea is the last supercontinent, which broke out 300 to 200 Ma ago to form the present-day continents. The assemblage and break out of supercontinents seem to affect the entire Earth system, by controlling sea level and chemistry, oceanic circulation, and climate, and possibly provoking mass extinctions or life explosions.

Supercritical Fluid

Henderson James Cleaves
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Georgia Institute of Technology, Center for
Chemical Evolution, Atlanta, GA, USA

Definition

A supercritical fluid is a substance at a temperature and pressure above its critical point. It can effuse through solids like a gas and dissolve materials like a liquid. Supercritical fluids thus have properties between those of a gas and a liquid.

Supercritical fluids have no surface tension, as there is no liquid/gas phase boundary. By changing the pressure and temperature of the fluid, the properties can become more liquid-like or more gas-like. The solubility of dissolved substances in a supercritical fluid tends to increase with the density of the fluid at a constant temperature. Since density increases with pressure, solubility tends to increase with pressure. The relationship with temperature is more complex. At constant density, solubility increases with increasing temperature. Close to the critical point, however, the density can drop drastically with slight increases in temperature. Thus, close to the critical temperature, solubility may drop with increasing temperature and then rise again.

Submarine hydrothermal vents are widely distributed on the ocean floor. Many lie at great depth where the tremendous pressure from the overlying seawater prevents the explosive release of steam and gas. In some cases, seawater can be heated to over 400–465 °C, where it becomes a supercritical fluid depending on the ambient pressure.

The atmosphere of Venus is composed of 96.5% CO₂ and 3.5% N₂. The surface pressure is 9.3 MPa, and the surface temperature is 735 K, well above the critical points of both gases; thus, the atmosphere near the surface is a supercritical fluid.

Keywords

Chandrasekhar mass · Collapse · Cosmology · Dense matter · Massive stars ·

Nucleosynthesis · Stellar evolution · Shock wave · Thermonuclear reactions · White dwarfs

Definition

Supernovae are cataclysmic explosions of stars at the end of their evolution. Two categories of stars are known to explode: massive ones ($M > 8\text{--}10 M_{\odot}$; $M_{\odot}$ is the solar mass) and white dwarfs (the remnants of low mass stars) if they can grow by accretion in a binary system. When they explode, supernovae inject energy into the ► [interstellar medium](#) and eject ► [heavy elements](#) such as carbon, oxygen, or ► [iron](#). Supernovae are one of the main contributors to the chemical evolution of galaxies.

History

Five times in the last millennium, a new star suddenly appeared in the sky. Initially very bright, it progressively declined to finally disappear after a few months or a few years. The first star, in 1006, was the brightest one, even visible during daytime. It was followed in 1054 by a new event described as a “guest star” by the Chinese astronomers. The remnant of this object is the famous Crab nebula in the Taurus constellation. A third, less bright supernova was seen in 1181. Then, nothing was noticed until 1572 when the Danish astronomer Tycho Brahe observed another new star in Cassiopeia and recorded his observations in Latin in his work, “De nova stella.” Only 32 years later, in 1604, Kepler studied the last one of these extraordinary events. We now know that they all were supernovae having exploded in our own galaxy, the ► [Milky Way](#). The modern study of supernovae started during the thirties with F. Zwicky (who coined the word supernova). He launched a search for supernovae in external galaxies which was very successful with more than 100 discoveries in about 30 years. In 1987, a supernova was found in the Large Magellanic Cloud, a small irregular satellite galaxy of

the Milky Way, 150,000 light years from us. Reaching magnitude 4.5 at its maximum, it was barely visible with the naked eye but still the brightest supernova since 1604.

Overview

Supernovae represent the end point of evolution of two main categories of stars: (1) the most massive ones ($M > 10 M_{\odot}$) which successively fuse hydrogen, helium, carbon, oxygen, neon, and silicon in their cores, eventually leading to the formation of a central core made of iron (Stars between 8 and $10 M_{\odot}$ do not burn oxygen but probably also produce a supernova by a different mechanism, resulting from the captures of electrons by the oxygen, neon, and magnesium nuclei present in their core). When this core approaches $1.4 M_{\odot}$, it becomes unstable and collapses. However, when the central density reaches a few times 10^{14} g/cm^3 (the density of nuclear matter), the core bounces and launches a strong shock wave outward which ejects the envelope at velocities exceeding 10,000 km/s. (2) The second category is white dwarfs (the remnants of stars with $M < 8 M_{\odot}$), which can explode if they accrete material from a companion star in a binary system. The accretion process can occur by progressive mass transfer from the companion or by true coalescence, if the binary is made of two white dwarfs. The ► [white dwarf](#) material (a mixture of carbon and oxygen) ignites ► [nuclear reactions](#) in an explosive way and the combustion propagates to the whole star, which is entirely destroyed. The first group represents the so-called core-collapse supernovae, while the second corresponds to “thermonuclear supernovae.” Besides their own interest, supernovae play a key role in the chemical and dynamical evolution of galaxies: they synthesize heavy elements and inject energy into the interstellar medium which triggers the formation of new stars. Cosmic rays are also accelerated in the shock waves present in their remnants. Due to their extreme luminosity (over 1 billion solar luminosities), they can be detected at very large distances and used for cosmological studies.

Basic Methodology

The nature of the stars ending their evolution as supernovae and the physical mechanisms responsible for the explosion are studied through a close interplay between observational and theoretical research. Spectroscopy provides clues on the progenitor stars (composition of the envelope) and energetics of the explosion (expansion velocity obtained through the Doppler effect). The light curve (i.e., the luminosity as a function of time) offers additional information on the sources of energy and constraints the mass and radius of the envelope.

The classification of supernovae was originally (and largely remains) based on spectroscopy. Hydrogen lines are absent from type I supernova spectra and present in type II. Moreover, type I supernovae have been divided into three subclasses: at maximum light (the peak of the light curve), type Ia (SN Ia) exhibit lines of intermediate mass elements (especially a bright silicon line) while they show mainly iron and cobalt lines at late times. Helium lines dominate SN Ib spectra at maximum light and are absent in SN Ic. Conversely, SN II have conspicuous hydrogen lines both at maximum light and at late times.

Population studies, which relate supernovae to their environment, show that SN Ib/c should be clearly distinguished from SN Ia. Like SN II, they are only observed in regions of ongoing star formation, contrary to SN Ia which are present in all kinds of environments, including elliptical galaxies which have not formed stars for several billion years. SN Ib/c and SN II progenitors should then be massive stars which only live a few million years and are therefore expected to explode close to their birthplace. The absence of hydrogen in SN Ib/c can be explained by mass loss due to stellar winds prior to the explosion. In SN Ib the helium layer lying below the lost hydrogen envelope remains, while in SN Ic it is also lost, leaving the “stripped” carbon and oxygen-rich core of the star.

The progenitors of SN Ia are low mass stars – the only ones remaining in an old stellar population – which should also be highly evolved to have lost all their hydrogen. This suggests an explosion scenario involving a white dwarf.

White dwarfs are the remnants of low mass stars ($M < 8 M_{\odot}$). They are perfectly stable when isolated but can become explosive if their mass is brought by accretion close to the Chandrasekhar limit ($1.4 M_{\odot}$; see ► [Chandrasekhar’s Limit](#)).

Theoretical models of SN Ib/c and SN II supernovae invoke the collapse of the central core of the star, which becomes a ► [neutron star](#) or even possibly a ► [black hole](#) (these supernovae are now globally called “core-collapse supernovae”). Most of the gravitational energy released in the collapse is carried away by neutrinos, but less than 1% of the total is sufficient to power the explosion. For SN Ia, a thermonuclear runaway which incinerates and destroys the whole star appears able to account for the major observational facts.

These various explosion mechanisms are studied by numerical simulations involving both a complex hydrodynamics (multidimensional treatment of the fluid motion) and input physics (equation of state of dense matter, neutrino transport). The general explosion scenarios outlined above are probably correct, but many questions are still unsolved and the study of supernovae remains an active research field.

Key Research Findings

Core-collapse and thermonuclear supernovae have very different explosion mechanisms, but the concept of Chandrasekhar mass plays a key role in both. It represents the maximum possible mass for an object “supported by electron pressure,” the interior of which is “degenerate.” In degenerate matter, the usual thermal pressure is replaced by a pressure of quantum origin, resulting from the impossibility for two electrons to be in the same quantum state (Pauli’s exclusion principle).

After successive episodes of nuclear burning (fusion), massive stars terminate their evolution having an “onion-shell structure” with a central degenerate iron core surrounded by non-degenerate layers of lighter elements from silicon (next to the core) to the outer hydrogen envelope, if it is present. Iron is the most stable nucleus and cannot undergo further burning. As a result of

silicon burning, the core mass grows – iron nuclei being the nuclear ashes of silicon – and eventually reaches the Chandrasekhar limit where it becomes unstable. It collapses in less than 1 s until the central density reaches a few times 10^{14} g/cm^3 (i.e., 100 million tons per cm^3 !). This corresponds to the density of nuclear matter, where nuclei are brought into contact with each other. Nuclear matter is strongly incompressible and provides an additional pressure which stops the collapse of the inner $0.6\text{--}0.8 M_{\odot}$ of the core. The outer core violently bounces on it and acts as a piston moving outward. A strong shock wave forms and it was initially believed that it carried enough energy to power the explosion. However, it was subsequently shown that, due to energy losses behind the shock (mainly the breakup of iron nuclei into free nucleons), the bounce alone was not able to produce an outburst. Additional energy coming from the neutrinos escaping from the cooling inner core was then invoked. Neutrino interaction with normal matter is very weak, but the extreme densities encountered in the shock region may allow the transfer of a small fraction of the neutrino energy to heat the core and restart the shock propagation. Unfortunately, numerical simulations of this process are so complex that no clear consensus has been reached among the different groups of experts: some get a successful explosion, while for others the material falls back.

White dwarfs are also made of degenerate material (a carbon-oxygen core surrounded by a helium layer in SN Ia progenitors), so that they become potentially explosive if their mass increases. This may happen if they receive material from a companion star by mass transfer in a binary system. Two evolutionary channels are a priori possible: slow accretion of matter outflowing from the companion or direct coalescence in a system of two white dwarfs. In the first case, carbon is ignited at the star center when the white dwarf approaches the Chandrasekhar limit. Nuclear burning in degenerate material is explosive and rapidly extends outward, the whole star being eventually destroyed. In the second case, coalescence results from the decrease of orbital separation caused by the emission of gravitational

radiation from the system. At some point, the less massive of the two white dwarfs (which has the largest radius) is disrupted and coalescence ensues in about 1 min. Nuclear fuel (first helium and then carbon and oxygen) ignites in the collision region and the combustion now proceeds inward. Again, the white dwarf is entirely destroyed.

A major uncertainty comes from the difficulty of estimating the velocity of propagation of the burning front. It can be supersonic (and then called a “detonation”) or subsonic (“deflagration”). Some models adopt a mixture of the two, starting with a deflagration which evolves into a detonation. Complete burning of the inner $0.6\text{--}0.8 M_{\odot}$ leads to ^{56}Ni , a radioactive isotope of nickel which decays into cobalt and iron, releasing energy which powers the light curve. The outer region undergoes incomplete burning leading to elements such as silicon or sulfur. This distribution of nucleosynthetic products agrees well with the results from spectroscopy.

Applications

- If stars did not explode, all the elements formed by nucleosynthesis during their lifetime (and during the explosion itself) would stay trapped in stellar interiors. Supernovae allow most of them to be ejected into the interstellar medium, which then gets progressively enriched in heavy elements (just after the Big Bang, the universe contained only hydrogen, helium, and very small fractions of deuterium, lithium, and beryllium). Carbon (the elementary brick of all organic molecules), oxygen, and silicon, for example, come from core-collapse supernovae, while SN Ia are the main providers of iron. It is remarkable to realize that all the atoms from which human beings are made (except hydrogen) were formed in stars which have disappeared before the solar system formed, 4.5 billion years ago. Supernovae also inject energy into the interstellar medium. They drive strong shock waves which create bubbles filled by hot gas. At the boundaries of these bubbles, the formation of new stars is triggered.

- Supernovae are so bright that they can be detected to cosmological distances. This is especially important in the case of SN Ia which are also considered to be reasonably good “standard candles,” that is, objects which all have the same luminosity. A plot of their apparent magnitude (at maximum light) as a function of redshift, called the Hubble diagram, can then be used to constrain cosmological models. This has shown that the expansion of our universe is accelerating (and not decelerating as was previously believed), which implies that space is pervaded by some form of “dark energy,” the nature of which remains unknown.

Future Directions

The details of the mechanism responsible for the explosion of core-collapse supernovae are still highly debated. Numerical simulations of the whole process are very difficult and only a few groups in the world are performing them. It has been recently realized that supernova explosions might be asymmetric due to a new kind of instability developing shortly after core bounce. It is also believed that this instability may greatly help obtain successful explosions as recently suggested by simulations in three dimensions. A related question concerns the separation between models giving a neutron star remnant and those collapsing to a black hole. What are the key factors controlling the fate of the star? Is the initial mass the only important parameter? How critical is the amount of rotation present in the core?

In the case of SN Ia, the respective roles of detonation and deflagration in the burning mechanism are still unclear, but the main issue remains the nature of the progenitors: standard accretion from a normal star and coalescence of a system of two white dwarfs represent two possible channels. We don't know how they contribute to the rate of SN Ia in different ► [stellar populations](#) and even if they always both contribute.

Supernova Remnant

Thierry Montmerle

Institut d'Astrophysique de Paris, Paris, France

Definition

In the optical domain, supernova remnants (SNR) appear as spectacular, bright filamentary nebulae, testifying to the past explosion of a star. There are two main types of SNRs, depending on the type of the explosion: (1) In “shell-type” SNRs, the nebula is hollow and filaments are arranged more or less in the form of concentric circular shells, and are interpreted as shock waves triggered by the explosion, propagating into the interstellar medium at velocities of up to a few 1000 km/s. Famous representatives of this class are the “Cygnus Loop” and the “Medusa” in the constellation Gemini. (2) In “filled-type” SNRs, also known as “plerions” (from a Greek word

meaning “full”), the nebula looks like a web of filaments of stellar origin, emanating from a bright center. Plerions contain a ► [pulsar](#) (a rotating, very condensed star called a “neutron star”). The most famous representative of the class is the “Crab nebula,” illustrated in Fig. 1. Supernova remnants are also conspicuous in the radio centimetric range and in X-rays. Since these wavelengths are much less sensitive to interstellar extinction than the optical, supernova remnants are known at large distances throughout the Galaxy. Many are also known in the galaxies nearest our own, the Magellanic Clouds.

History

Today nearly 300 SNRs are known, the majority having estimated ages from several thousand to several hundred thousand years. Six supernova explosions have been witnessed with a naked eye in historical times, many being recorded by Chinese astronomers, like the Crab nebula in AD

Supernova Remnant,

Fig. 1 The “Crab Nebula,” in the Taurus constellation is the remnant of a supernova that exploded in 1054 AD. The filaments are the remains of the parent star, and the diffuse light is due to energetic electrons accelerated by the central pulsar. (Photograph ESO Very Large Telescope)

1054. The first one was recorded in AD 185, and the last appeared in 1987 in the Large Magellanic Cloud. Two more are known to have exploded in the Milky Way during historic times (around 1671 and 1870), but were not seen because of the high interstellar dust obscuration.

Supernova Types

Nikos Prantzos
Institut d'Astrophysique de Paris, Paris, France

Definition

Supernovae are classified according to their early spectra as Type I (SNI) or Type II (SNII), depending on the absence or presence of hydrogen, respectively. SNI are further divided into SNIa (Si present), SNIb (Si absent, He present), and SNIc (Si and He absent, C present). It turns out that SNIa correspond to thermonuclear explosions of ► [white dwarfs](#) in binary systems, while all other types result from the gravitational collapse of the core of a massive star that has lost various amounts of its envelope (little H in SNII, all of H in SNIb, and all of H and He in SNIc). It is expected that in a galaxy like the Milky Way, 2 SN per century explode, SNIa are five times less frequent than gravitational supernovae and (SNIb+SNIc) are three times less frequent than SNII.

Definition

Superrotation refers to the state in which the atmosphere of a planet or a satellite has an angular velocity much higher than that of the body or a much shorter period of rotation than that of the body.

Overview

All planets and satellites rotate around an axis with very different periods, the longest is that of Venus with 243 days and the shortest is that of Jupiter with 9.92 h. An atmosphere that does not move with respect to the direction of rotation is in solid body rotation (i.e., is in corotation with the underlying planet surface or the planet itself). If the atmosphere moves with respect to the rotation of the body, it is in a super- or sub-rotating state depending on the rotation direction. If the motion takes place in the same direction as the rotation of the planet, it is prograde (retrograde if it is in the opposite sense). To characterize the magnitude of this phenomenon on each planet, one can use different types of indexes (Read and Lebonnois 2018). A simple way to characterize the state of rotation of an atmosphere is to consider the mean

Superrotation, Table 1 Planetary parameters and superrotation index

Planet or satellite	R (km)	Rotation period τ_p	Equatorial zonal velocity U – rotational period τ_{ATM}	Index s
Venus	6052	−243.01 days	−110 m/s – 4 days	61.8
Earth	6371	23.93 h	−20 m/s – 25 h	0.96
Mars	3396	24.62 h	30 m/s – 21.9 h	1.1
Jupiter	71,400	9.84 h	100 m/s – 9.76 h	1.01
Saturn	60,330	10.65 h	450 m/s – 10.19 h	1.05
Uranus	25,562	17.23 h	−50 m/s – 17.57 h	0.98
Neptune	24,622	17.24	−400 m/s – 20.54 h	0.8
Titan (Saturn satellite)	2576	15.95 days	100 m/s – 350 m/s 1.68 – 0.52 days	9.5–30.7
HD 209458b	94,380	3.52 days	2000 m/s – 1.74 days	2.03

motion velocity in its equatorial region at a given altitude level. For example, through the ratio of the rotational period of the body τ_p to the rotation period of the atmosphere τ_{ATM} . The atmospheric rotation period is given by $\tau_{ATM} = 1/((U/2\pi R) + (1/\tau_p))$ where U is the zonal velocity relative to the body (zonal means in the direction of the parallels). Table 1 shows the value of the rotation index $s = \text{period planet } (\tau_p)/\text{period atmosphere } (\tau_{ATM})$ for solar system planets, one satellite, and one exoplanets of the “hot Jupiters” type.

According to this scheme, Venus atmosphere is at the upper cloud level (altitudes about 60–70 km above surface) under an extreme superrotation. Its motion state has been measured remotely tracking clouds and using the Doppler effect and in situ by descending probes (Sánchez-Lavega et al. 2017). Titan is the major satellite of Saturn and is covered by a thick haze layer. Atmospheric velocities are measured in the altitude range from 200 to 1000 km by a variety of techniques that use the Doppler effect (Lellouch et al. 2019). They show the presence of high wind speeds along this large altitude range. The Huygens entry probe also measured high wind speeds at 145 km altitude level (Folkner et al. 2006), confirming the high superrotating state of this atmosphere. Earth and Mars equatorial lower atmospheres have moderate mean zonal winds (Schneider 2006; Mitchell et al. 2019; Barnes et al. 2017) showing low sub- and superrotation states, respectively. However,

intense eastward jets occur on both planets at mid-latitudes that are seasonally dependent on Mars. The giant planets Jupiter and Saturn exhibit a pattern of zonal jets alternating in their direction with latitude (Sánchez-Lavega et al. 2019). Cloud tracking is the standard method to measure winds in the giant and icy planets. Jupiter and Saturn have broad and high-speed equatorial jets. Their atmospheres are in a low superrotation state according to the definition above since these planets are rapidly rotating bodies. The situation is different for the giant “hot Jupiter” exoplanet HD209458b that, being close to its star should have its spin synchronized to the orbital period (Showman et al. 2010). Intense winds should blow from the hottest to the colder side of the planet implying a superrotation state. The icy planets Uranus and Neptune show retrograde equatorial jets, then they are subrotating relative to their bodies (Sánchez-Lavega et al. 2019; Hueso and Sánchez-Lavega 2019).

Different mechanisms have been proposed to explain the extreme superrotating states of Venus, a planet close to the Sun and subjected to high insolation, and the satellite Titan that is far and cold. They involve global meridional overturning circulations and nonaxisymmetric eddies to transport momentum upward and equatorward in these atmospheres but the details are not known and may differ between them (Read and Lebonnois 2018).

Acronyms

CRESU (French acronym for uniform supersonic flow reactor for chemical kinetics studies)

Definition

A **jet** is generated when expanding a gas through a nozzle, from a high-pressure reservoir into a low-pressure medium. The flow is called **supersonic** when the **Mach number** (the ratio of final velocity after expansion to **the sound velocity** at the final temperature) is higher than 1. This condition is fulfilled when the pressure in the reservoir is sufficiently high so that many collisions occur within the nozzle, resulting in an efficient conversion of the initial energy content of the gas into kinetic energy along the nozzle axis. In the context of laboratory astrophysics, supersonic beams are used to measure chemical kinetics at low temperature (CRESU technique), to facilitate spectroscopic data determination (as the rotational temperature is low), to study photodissociation or ionization processes, and to explore the dynamics of reactions or inelastic processes with crossed supersonic molecular beams: The collisional processes are studied under physical conditions

(pressure and temperature) relevant for many interstellar media, thus providing a stringent test for input data of astrophysical models, calculated with quantum methods.

History

The history of (*atomic or molecular*) jets is nicely introduced by Otto Stern (1943 Nobel Prize in Physics) and also by Dudley R. Herschbach (1986 Nobel Prize in Chemistry) who gives a nice historical background in his Nobel Lecture.

Surface Gravity

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

Surface gravity is defined as the acceleration of a test mass in free fall at the surface of a massive

body under the gravitational force produced by the body. Noted g , the surface gravity for a spherical body is derived from Newton's formula $g = G M/R^2$, where G is the gravitational constant and M and R are the mass and radius of the massive body. Unit: m s^{-2} . The surface gravity on Earth is equal to 9.81 m s^{-2} .

Surface Plasmon Resonance

Nita Sahai

Department of Polymer Science, University of Akron, Akron, OH, USA

Synonyms

[SPR](#)

Definition

Surface Plasmon Resonance (SPR) spectroscopy is based on excitation of electronic oscillations by light at a planar interface between two materials for which the real part of the dielectric constants has opposite signs (e.g., metal/vacuum or metal/air). The electromagnetic waves that travel parallel to the interface are reflected by total internal reflection, and the evanescent wave probes the interface. The reflected intensity decays exponentially as a function of distance away from the interface. SPR is, therefore, a very sensitive probe of changes in the interfacial roughness due to adsorption of large molecules, such as polymers and proteins, on the metal surface. This technique is the basis of many lab-on-a-chip and biosensor applications.

Synonyms

[Viability](#)

Definition

The term “survival” describes a capability of individuals, communities, or whole populations of staying alive over a certain period of time. In astrobiology “survival” is mainly applied to microorganisms – individuals or communities – that withstand hostile environmental conditions. Several microorganisms are capable of forming dormant states, e.g., bacterial spores, of high resistance to temporarily unfavorable conditions.

Overview

During the about 3.5 billion years history of life on Earth, microorganisms have developed a variety of adaptive strategies to survive in environments that are toxic to most other life-forms. There are two ways of responses of microorganisms to extreme conditions: (1) capability of growth, i.e., the maintenance of an active population, which finds its optimum or near optimum conditions in those environments, and (2) capability of survival for short or even extended periods of time in a dormant state (Table 1). Examples for the latter one are spores produced by fungi and bacteria, cysts produced by various eukaryotes, and seeds produced by plants. Most of these forms are usually unicellular bodies – exceptions

Survival, Table 1 Environmental range allowing growth or survival of at least some species of microorganisms

Parameter	Growth	Survival
Temperature (°C)	−20 to +113	−262 to +113
Pressure (Pa)	10 ⁵ –10 ⁸	10 ^{−7} to ≥10 ⁸

Survival, Fig. 1 Survival curves for *Deinococcus radiodurans* R1 and its recombination-deficient mutant Rec 30 compared to survival curves for spores of *Bacillus subtilis* and cells of *Escherichia coli* B/r following exposure to X-rays. (From Horneck and Baumstark-Khan 2002)

are seeds – which are encased by a thick protective coat. They are very resistant to environmental extremes, such as heat, ► [desiccation](#), radiation, and other stresses. Bacterial ► [spore](#) formation represents a strategy by which a bacterium escapes temporally and/or spatially from unfavorable conditions, resulting in incredible longevity – survival times of 25–250 Ma have been reported (Cano and Borucki 1995; Nicholson et al. 2000; Vreeland et al. 2000).

The survival capacity of microorganisms in response to stressors is quantified in survival curves, which give the survival rate as a function of the dose of the applied agent (Fig. 1). The bacterium *Deinococcus radiodurans* has been

known as the most resistant organism in response to ionizing radiation, tolerating doses up to 4 kGy without a decrease in survival.

The exceptionally high resistance against environmental extremes over long periods of time makes bacterial spores suitable candidates for astrobiology studies, such as the likelihood of transport of life between the planets of our solar system, i.e., the hypothesis of ► [lithopanspermia](#), and ► [planetary protection](#) considerations. Experiments in space and at ground simulation facilities as well as model calculations have shown that spores would survive a hypothetical interplanetary transfer, including shock waves and high temperatures during the ejection process

(Horneck et al. 2008), extreme vacuum, intense radiation, and varying temperatures during the journey in space (Mileikowsky et al. 2000), and finally accelerations and high temperatures during entry and landing on another planet (Westall and de la Torre Noetzel 2008; Horneck et al. 2010). Desiccation-resistant organisms, such as bacterial spores and ► [lichens](#), survive especially well in the hostile space environment because of their low water content and the protection by outer thick layers.

Definition

A Svedberg unit (represented as S or sometimes Sv) is a non-Système Internationale unit for sedimentation rate. The unit is named after Swedish chemist Theodor Svedberg (1884–1971), who won the 1926 Nobel Prize in chemistry for his work on colloids and the invention of the ultracentrifuge. The sedimentation rate is a measure of how quickly a particle sediments from a solution or suspension under the induced gravitational field of a centrifuge.

The sedimentation coefficient is the ratio of the speed of a substance in a centrifugal field to its acceleration in comparable units. A substance with a sedimentation coefficient of 1S (10^{-13} s) will travel at 1 mm per second (10^{-6} m s $^{-1}$) under the influence of an acceleration of 10^6 G (10^7 m s $^{-2}$). Centrifugal acceleration is given as ωr^2 , where r is the radial distance from the rotation axis and ω is the angular velocity in radians s $^{-1}$.

Though the Svedberg unit is technically a measure of time (10^{-13} s), it also offers a measure of particle size, density, and shape, as these aspects

of a particle contribute to sedimentation behavior. All other things being equal, larger particles tend to sediment faster and thus have higher Svedberg values.

The Svedberg has commonly been used to distinguish among the ribosomes found in the different domains of life, as well as the relative sizes of their subunits.

Symbiosis

Juli Peretó
Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Synonyms

[Mutualism](#)

Definition

Symbiosis is the association of two or more species, resulting in a new entity. The relationship can be metabolic or genetical and may lead to a continued association, from generation to generation. In a more restricted sense, it refers to cases in which all the associated partners obtain benefits (mutualism). But the nature of the association can be detrimental to some of the partners (parasitism) or neutral (commensalism). The association can also be optional (facultative) or obligate. Symbiosis is widespread in nature and plays a central role in the origin of evolutionary innovations. The case of intracellular symbionts (► [endosymbiosis](#)) represents a mechanism for the origin of the eukaryotic complexity.

Synchronous Rotation

Emeline Bolmont
Observatoire de Genève, Université de Genève, Sauverny, Switzerland

Synonyms

[Tidal locking](#)

Definition

Synchronous rotation or tidal locking occurs when the rotation period of a body (planet or satellite) is equal to its orbital period. When a planet is synchronously rotating, it is always showing the same side to the star so that the region facing the star is in a permanent dayside and the opposite region is in a permanent night side.

The rotation of a planet reaches synchronization as a result of tidal interaction with the host star (e.g., Hut 1981). The timescale of synchronization is relatively short compared to the circularization timescale. Note that synchronization occurs for planets/satellites with a low eccentricity (e.g., Makarov and Efroimsky 2013). If the eccentricity of the planet is significantly nonzero, other types of rotations are to be expected, in particular spin-orbit resonances (like Mercury, which rotates three times on itself while it orbits twice the Sun). But then we do not speak of tidal locking, but use rather the more generic term of spin-orbit resonances. The major satellites of the solar system are all synchronously rotating (like the Moon) and all close-in exoplanets are usually thought to have reached this rotation.

This has important implications for the climate of close-in planets and particularly in the context of planets in the Habitable Zone (HZ) of low mass stars like Proxima and TRAPPIST-1. Due to the low luminosity of low-mass stars, the HZ is located close-in, so that the temperate planets are thought to be tidally locked. In particular, the planets of TRAPPIST-1 have a low eccentricity and they are thought to have reached a synchronous rotation in less than a million year after the formation of the planets (while the system is thought to be several gigayears old). Due to the very specific insolation pattern (permanent day and night sides), tidally locked planets have different climates from what we know in the solar system.

In particular, it has been proposed by Yang et al. (2013) that considering a tidally locked planet changes the distance of the inner edge of the classical HZ: it moves closer to the star. In other words, a synchronous planet could sustain surface liquid water even if it receives more energy than the runaway greenhouse limit. This is due to the presence of clouds above the substellar point, which act to increase the reflective power of the planet and thus lower the surface temperature.

The climate of a tidally locked planet in the HZ of its star strongly depends on the amount of carbon dioxide and the total amount of water present on the planet. Depending on these amounts, there are several outcomes regarding

the presence of surface liquid water (see Turbet et al. 2016 for a visual representation of these states):

- For a very small amount of water (around 10^{-5} times the Earth ocean content), no liquid water can exist on the surface of the planet whatever the amount of carbon dioxide. For low CO_2 content, the dayside is completely dry and there are glaciers on the night side (cold trap on the nightside, see also Leconte et al. 2013). For very low CO_2 content and without background gas (like N_2), CO_2 can also condense on the night side. For high CO_2 content, all water is in vapor state.
- Increasing the amount of water, a new possibility appears for intermediate CO_2 content: the dayside remains dry but the night side can sustain surface liquid water. This situation would mean that the planet is habitable in the astronomical sense, but the repercussions for the origin of life are not clear. This liquid water would never be submitted to stellar radiation.
- Increasing the amount of water (few percent of Earth ocean content), liquid water can be found on the dayside for intermediate CO_2 content.
- For high content of water ($>10\%$ of Earth ocean content), liquid water can be found on the planet unless the CO_2 amount is very high, for which case the water is in vapor state. For lower amount of CO_2 , the planet is either an ice-free ocean or partially covered with ice.

If there is a background gas (like nitrogen), the cases with low CO_2 content would be slightly different: the background gas would favor heat redistribution and it would impede the extent of the water ice and could also prevent the condensation of the CO_2 reservoir on the night side.

Definition

A synchrotron accelerator is a particular type of cyclic particle accelerator in which the magnetic field and the electric field are carefully synchronized with the traveling particle beam. While a cyclotron uses a constant magnetic field and a constant-frequency applied electric field, both of these fields are varied in the synchrotron. By increasing these parameters appropriately as particle energy increases, the path of the particles can be held constant as they are accelerated. This allows the vacuum chamber for the particles to be a torus. A path of large effective radius can then be constructed using simple straight and curved pipe segments, unlike the disk-shaped chamber of cyclotrons.
